This work is provided "as is," and the publisher disclaims any and all warranties, express or implied, including any warranties as to accuracy, comprehensiveness, or currency of the content of this work.

This work is no substitute for individual patient assessment based on health care professionals' examination of each patient and consideration of, among other things, age, weight, gender, current or prior medical conditions, medication history, laboratory data, and other factors unique to the patient. The publisher does not provide medical advice or guidance, and this work is merely a reference tool. Health care professionals, and not the publisher, are solely responsible for the use of this work including all medical judgments and for any resulting diagnosis and treatments.

Given continuous, rapid advances in medical science and health information, independent professional verification of medical diagnoses, indications, appropriate pharmaceutical selections and dosages, and treatment options should be made, and health care professionals should consult a variety of sources. When prescribing medication, health care professionals are advised to consult the product information sheet (the manufacturer's package insert) accompanying each drug to verify, among other things, conditions of use, warnings, and side effects and identify any changes in dosage schedule or contraindications, particularly if the medication to be administered is new, infrequently used, or has a narrow therapeutic range. To the maximum extent permitted under applicable law, no responsibility is assumed by the publisher for any injury and/or damage to persons or property, as a matter of products liability, negligence law or otherwise, or from any reference to or use by any person of this work.

Preface

When H. Houston Merritt first published this *Textbook of Neurology* in 1955, he was the sole author. The book became popular, and he revised it himself through the fourth edition. The body of neurologic knowledge increased and, in the fifth edition, he finally accepted contributions from colleagues. Even then, he wrote most of the book himself, and he continued to do so for the sixth edition despite serious physical disability. He died in 1979, just as the sixth edition was released for distribution.

The seventh edition, published and edited in 1984 by Lewis P. Rowland, was prepared by 70 of Merritt's former students, almost all with ties to Columbia University. Thirty of them headed neurology divisions or departments, and others had become distinguished clinicians, teachers, and investigators. That edition established Merritt's legacy as a singular leader whose career had set models for clinical investigation (when it was just beginning), clinical practice, teaching, editing books and journals, administering departments and medical schools, and commitment to national professional and voluntary health organizations.

Just as Houston Merritt did, "Bud" Rowland served as chief editor for the next five editions of the book. During that 30-year span, *Merritt's Textbook of Neurology* became firmly established as a classic the world over. At the same time, as codirector at the Neurological Institute of New York at Columbia University, Rowland trained and inspired a new generation of academic and practicing neurologists, edited the journal *Neurology* and served as an associate editor for *The New England Journal of Medicine*, and was a prolific researcher and writer in his own right, authoring hundreds of scientific articles.

In 2016, Rowland handed off the lead editing duties of the 13th edition of Merritt's textbook to Drs Elan D. Louis and Stephan A. Mayer while continuing to serve as a coeditor. The 13th edition represented a thorough modernization and substantial reboot compared to previous editions. We substantively broadened the authorship base beyond those who had trained or worked at Columbia, tapping into the best expertise across the country. More importantly, we added new focus to the mission of *Merritt's Textbook of Neurology*: While retaining its best elements and traditions, we aimed to create the essential modern neurology textbook with a global worldview.

Gone were the largely descriptive chapters and black and white photos of prior editions. The 13th edition blossomed into full color and featured a completely revamped table of contents, including an opening chapter entitled "Worldwide Epidemiology of Neurologic Disease," new chapters related to acute neurology and neurocritical care, and a new section in the front of the book entitled "Common Problems in Neurology." The 13th edition also emphasized patient management based on evidence-based guidelines, helpful diagnostic and treatment algorithms, management checklists, and practical pearls. We added for the first time numbered LEVEL 1 citations to back up all diagnostic and management recommendations based on high-quality clinical trials, evidence-based practice guidelines, or meta-analyses.

Lewis P. Rowland died in 2017 at the age of 91 years, 1 year after publication of the 13th edition. Clinical neurology continues to rapidly advance on multiple fronts, and we welcome Dr James Noble of Columbia University as a coeditor. Dr Noble, a cognitive neurologist and experienced educator, taught in clinical conferences with Dr Rowland until just weeks before his death. His inclusion builds on the longstanding tradition of *Merritt's Neurology* serving as an important tool in clinical neurology education. As students and admirers of "Bud" Rowland, we are proud to dedicate this 14th edition of *Merritt's Textbook of Neurology* to Dr Rowland. As with any dynamic book, the list of authors has continued to expand, to more than 180 authors for this 14th edition. Although many were trainees or have worked at Columbia University, we have continued to invite authors who are world-recognized leading experts. Along the same lines, we have sought to maintain Houston Merritt's literary style: direct, clear, and succinct writing; emphasis on facts rather than unsupported opinion; and ample use of illustrations and tables.

Other changes with this 14th edition of Merritt's include the continued evolution of the book's unique and colorful visual style, featuring even more algorithms, flowcharts, illustrations, and videos. The book is designed for access from tablet, phone, and computer screens with enhanced navigation, search, and annotation tools. The chief idea for our readers is to provide curated, clinically rich information at the bedside, office, and even virtual clinical session—when and where clinicians need it. The Internet is full of information, but it is difficult to sort through. Merritt's provides trusted and cohesive information from expert all in a single place.

This edition of Merritt's is fully updated and includes comprehensive revisions reflecting remarkable progress made in recent years in neurology research, including new and emerging treatments for diseases previously without effective pharmacotherapy. New material includes updates on imaging and interventional therapy for stroke, the latest approved agents for migraine, epilepsy, and multiple sclerosis and new material on neurologic care in the developing world, neuro–coronavirus disease, septic encephalopathy, and addiction medicine.

We thank all the authors for their devoted and skillful work. We also thank the many section editors for their thoughtful guidance and painstaking efforts.

This project would never have moved forward without the help of many people at Wolters Kluwer. Indeed, a full roster of people has been involved in the project, from its conception to completion. These include Chris Teja (acquisitions editor), Tim Rinehart and Ariel S. Winter (product development editors), Maribeth Wood (editorial assistant), Stephen Druding (design coordinator), Harold Medina (production project manager), and Kirsten Watrud (marketing manager). Special thanks should go to Andrea Vosburgh, who initially brought the 13th edition and the concept of a complete overhaul of the book to fruition.

In addition to Dr Lewis P. Rowland, Dr Louis also dedicates this book to his late father, Dr Sydney Louis, an academic neurologist who inspired his career in neurology—a role model as a humanist, an educator, a perceptive clinician with a keen eye for nuance and detail, and a patient-centered physician. Countless friends and colleagues with whom we have worked at The Neurological Institute of New York at Columbia University over the years deserve credit for inspiring us, most notably John Brust, E. Sander Connolly, Stanley Fahn, Matthew E. Fink, Laura Lennihan, Linda Lewis, Karen Marder, J. P. Mohr, Timothy Pedley, Robert A. Solomon, and Olajide Williams. Dr Louis would like to thank Bettina Evans, at Yale University, whose tireless efforts early on ensured that spreadsheets would be organized and authors contacted in a timely manner, and Dr David Hafler, chair of the Department of Neurology at Yale, for providing support for the project as this edition was being prepared.

Finally, we would like to personally dedicate this book to the spouses and children of all the contributors and especially to our own families. Dr Louis would like to gratefully acknowledge the wise advice and loving support of his wife, Dr Avra Louis, and that of his children, Devin, Ravi, and Kiran. The Mayer family includes Dr Elissa Fory and children, Philip, Catherine, Chloe, and Soren. Dr Noble thanks his family for support including his wife Anne and their children Josephine, Salvatore, Benicio, and Beatrice.

Section Editors

Neeraj Badjatia, MD, MS, FANA, FCCM, FNCS
Chief of Neurocritical Care, Program in Trauma
Professor and Vice Chair, Department of Neurology
University of Maryland School of Medicine
Baltimore, Maryland

Carl W. Bazil, MD, PhD
Professor
Department of Neurology
Columbia University
New York, New York

Thomas H. Brannagan III, MD
Professor of Neurology
Director, Peripheral Neuropathy Center, Department of Neurology
Columbia University, College of Physicians and Surgeons
Co-Director, EMG laboratory
NewYork-Presbyterian Hospital
New York, New York

John C. M. Brust, MD
Professor

Jasmin Jo, MD
Affiliate Associate Professor
Division of Hematology/Oncology, Department of Internal Medicine, Brody School of Medicine
East Carolina University
Physician Lead, Neuro-oncology
Division of Hematology/Oncology, Department of Internal Medicine
Vidant Medical Center
Greenville, North Carolina

Michael G. Kaiser, MD, FAANS, FACS
Sub-specialty Director of Spine Surgery
Neurosurgery
The Valley Hospital
Ridgewood, New Jersey

Thomas J. Kaley, MD
Vice Chair for Clinical Research
Neurology
Memorial Sloan Kettering Cancer Center
New York, New York

Un Jung Kang, MD
Founders Professor of Neurology
Department of Neurology, Neuroscience and Physiology
New York University Grossman School of Medicine
Attending Physician
Department of Neurology
NYU Langone Health
New York, New York

Gurmeen Kaur, MD
Assistant Professor
Department of Neurology, Neurosurgery and Radiology
New York Medical College
Attending Physician
Department of Neurology and Neurosurgery
Westchester Medical Center
Valhalla, New York

Kavneet Kaur, MD
Medical Director
Department of Neurology
Garnet Health Medical Center
Middletown, New York

Steven G. Kernie, MD
Professor of Pediatrics (in Neurology)
Department of Pediatrics
Columbia University Vagelos College of Physicians and Surgeons
Chief, Critical Care and Hospital Medicine
NewYork-Presbyterian Morgan Stanley Children's Hospital
New York, New York

Imad Khan, MD
Assistant Professor
Departments of Neurology and Neurosurgery
University of Rochester School of Medicine and Dentistry
Attending Physician
Neuromedicine Intensive Care Unit
Strong Memorial Hospital
Rochester, New York

Alexander G. Khandji, MD, FACR
Professor of Radiology in Neurological Surgery and Neurology
Department of Radiology
Columbia University
Clinical Director
Department of Radiology
NewYork-Presbyterian Hospital
New York, New York

Inna Kleyman, MD
Assistant Professor
Department of Neurology
Columbia University
Attending Physician
Department of Neurology
NewYork-Presbyterian Hospital
New York, New York

Brian B. Koo, MD
Associate Professor of Neurology
Department of Neurology
Yale University
New Haven, Connecticut

Barbara S. Koppel, MD
Clinical Professor of Neurology
Department of Neurology
New York Medical College
Valhalla, New York

Rupesh Kotecha, MD
Associate Professor
Department of Radiation Oncology
Florida International University Herbert Wertheim College of Medicine
Chief of Radiosurgery
Director of CNS Metastasis
Department of Radiation Oncology
Miami Cancer Institute, Baptist Health South Florida
Miami, Florida

Andreas H. Kramer, MD, MSc, FRCPC
Clinical Associate Professor
Departments of Critical Care Medicine & Clinical Neurosciences
University of Calgary
Calgary, Alberta, Canada

William Charles Kreisl, MD
Assistant Professor of Neurology
The Taub Institute for Research on Alzheimer's Disease and the Aging Brain
Columbia University Irving Medical Center
Attending Neurologist
Department of Neurology
NewYork-Presbyterian/Columbia University Irving Medical Center
New York, New York

Sheng-Han Kuo, MD
Assistant Professor
Department of Neurology
Columbia University
New York, New York

Shouri Lahiri, MD
Assistant Professor
Departments of Neurology, Neurosurgery, and Biomedical Sciences
Cedars-Sinai Medical Center
Interim Director, Neurocritical Care
Departments of Neurology, Neurosurgery, and Biomedical Sciences
Cedars-Sinai Medical Center
Los Angeles, California

Michael W. Lawlor, MD, PhD
Professor
Pathology
Medical College of Wisconsin
Milwaukee, Wisconsin

Matthew R. Leach, MD
Neurocritical Care Fellow
Department of Critical Care Medicine
University of Pittsburgh
Neurocritical Care Fellow
Department of Critical Care Medicine
UPMC Presbyterian Hospital
Pittsburgh, Pennsylvania

Kiwon Lee, MD
Professor of Neurology
Department of Neurology
Rutgers, The State University of New Jersey
Chief of Neurology Service
Department of Neurology
Robert Wood Johnson University Hospital
New Brunswick, New Jersey

Oren Levy, MD, PhD
Assistant Professor (Adjunct)
Department of Neurology
Columbia University Irving Medical Center
New York, New York

Peter A. LeWitt, MD, MMedSc
Professor of Neurology, and Sastry Foundation Endowed Chair in Neurology
Wayne State University School of Medicine
Detroit, Michigan

Lillian Liao, MS
Medical Student
Department of Neurosurgery
Columbia University
New York, New York

Angela Lignelli, MD
Associate Professor
Department of Radiology
Columbia University
Neuroradiology Division Chief
Department of Radiology
NewYork-Presbyterian Hospital
New York, New York

Richard B. Lipton, MD
Edwin S. Lowe Professor and Vice Chair
Department of Neurology
Albert Einstein College of Medicine
Director, Montefiore Headache Center
Department of Neurology
Albert Einstein College of Medicine/Montefiore Medical Center
Bronx, New York

Vivian P. Liu, MD
Newport Beach, California

Erin E. Longbrake, MD, PhD
Assistant Professor
Department of Neurology
Yale University
New Haven, Connecticut

Elan D. Louis, MD, MS
Professor of Neurology
Linda and Mitch Hart Distinguished Chair in Neurology
Chairman, Department of Neurology
University of Texas Southwestern Medical Center
Dallas, Texas

Hani Malone, MD
Department of Neurosurgery
Scripps Clinic
Department of Neurosurgery
Scripps Green Hospital
La Jolla, California

Arthur M. Mandel, MD, PhD
Assistant Professor of Neurology at CUIMC
Department of Neurology, Division of Child Neurology
Columbia University
Assistant Professor
Department of Neurology, Division of Child Neurology
NewYork-Presbyterian Morgan Stanley Children's Hospital
New York, New York

Christopher E. Mandigo, MD, MS
Assistant Professor of Clinical Neurosugery
Department of Neurological Surgery
Columbia University
New York, New York

Karen S. Marder, MD, MPH
Sally Kerlin Professor Department of Neurology and Taub Institute on Alzheimer's Disease and the Aging Brain
Columbia University
New York, New York

Steven Marks, MD
Section Co-Chief, Cerebrovascular Diseases
Department of Neurology
Westchester Medical Center
Valhalla, New York

Maria Martinez-Lage, MD
Assistant Professor
Department of Pathology
Harvard Medical School
Assistant Pathologist, Associate Residency Program Director
Department of Pathology
Massachusetts General Hospital
Boston, Massachusetts

Paul G. Mathew, MD, DNBPAS, FAAN, FAHS
Assistant Professor
Department of Neurology
Harvard Medical School
Headache Specialist
Department of Neurology
Brigham and Women's Hospital/Harvard Vanguard Medical Associates
Boston, Massachusetts

Stephan A. Mayer, MD, FCCM, FNCS
Director of Neurocritical Care and Emergency Neurological Services
Westchester Medical Center Health Network
Professor of Neurology and Neurosurgery
New York Medical College
Valhalla, New York

Aurélien Mazeraud, MD, PhD
Fellow
Université de Paris
Fellow
Neuroanesthesia and Neurointensive Care Unit
GHU Paris Psychiatrie et Neurosciences
Paris, France

Paul C. McCormick, MD, MPH
Herbert and Linda Gallen Professor of Neurological Surgery
Department of Neurological Surgery
Columbia University Vagelos College of Physicians and Surgeons
Director, The Spine Hospital at the Neurological Institute of New York
Department of Neurological Surgery
NewYork-Presbyterian/Columbia University Irving Medical Center
New York, New York

J. Ricardo McFaline-Figueroa, MD, PhD
Instructor in Neurology
Department of Neurology
Brigham and Women's Hospital, Harvard Medical School
Physician
Center for Neuro-Oncology
Dana-Farber Cancer Institute
Boston, Massachusetts

Andrew McKeon, MD
Professor
Departments of Laboratory Medicine and Pathology, and Neurology
College of Medicine, Mayo Clinic
Consultant
Departments of Laboratory Medicine and Pathology, and Neurology
Mayo Clinic
Rochester, Minnesota

Minesh P. Mehta, MD, FASTRO
Professor and Chair
Department of Radiation Oncology
FIU Herbert Wertheim College of Medicine
Chief and Deputy Director
Department of Radiation Oncology
Miami Cancer Institute, Baptist Health South Florida
Miami, Florida

Merrick E. Miles, MD
Assistant Professor of Anesthesiology
Department of Anesthesiology
Vanderbilt University Medical Center
Associate Medical Director, Neuro Intensive Care Unit
Department of Anesthesiology
Vanderbilt University Medical Center
Nashville, Tennessee

Heather E. Moss, MD, PhD
Associate Professor
Departments of Ophthalmology and Neurology and Neurological Sciences
Stanford University
Attending Physician
Byers Eye Institute at Stanford
Stanford Health Care
Palo Alto, California

Shibani S. Mukerji, MD, PhD
Assistant Professor
Department of Neurology
Harvard Medical School
Associate Director, Neuroinfectious Diseases Unit
Department of Neurology
Massachusetts General Hospital
Boston, Massachusetts

Philip R. Muskin, MD, MA
Professor
Department of Psychiatry
Columbia University Irving Medical Center
Senior Consultant
Consultation-Liaison Psychiatry
Columbia University Irving Medical Center
New York, New York

Lakshmi Nayak, MD
Assistant Professor
Department of Neurology
Harvard Medical School
Director, Center for CNS Lymphoma
Senior Physician, Center for Neuro-Oncology
Dana-Farber Cancer Institute
Department of Neurology
Brigham and Women's Hospital
Boston, Massachusetts

Eric Newman, MD
Neuroradiology Fellow
Department of Radiology
NewYork-Presbyterian Hospital
New York, New York

James M. Noble, MD, MS, CPH, FAAN
Associate Professor of Neurology at CUIMC
Taub Institute for Research on Alzheimer's Disease and the Aging Brain
G.H. Sergievsky Center
Department of Neurology
Columbia University Irving Medical Center
Columbia University Vagelos College of Physicians and Surgeons
NewYork-Presbyterian Hospital
New York, New York

Setareh Salehi Omran, MD
Assistant Professor of Neurology
Department of Neurology
University of Colorado School of Medicine
Aurora, Colorado

Maria A. Oquendo, MD, PhD
Professor and Chairman
Department of Psychiatry
Perelman School of Medicine, University of Pennsylvania
Chief Psychiatrist
Department of Psychiatry
University of Pennsylvania
Philadelphia, Pennsylvania

Natalie Organek, DO
Neurocritical Care
Houston Methodist
Houston, Texas

Maryam Oskoui, MD, MSc
Associate Professor
Departments of Pediatrics and Neurosciences
McGill University
Director
Division of Pediatric Neurology
McGill University Health Center
Québec, Canada

Alison M. Pack, MD, MPH
Professor
Department of Neurology
Columbia University Irving Medical Center
Attending Physician
Department of Neurology
NewYork-Presbyterian Hospital
New York, New York

Gunjan Y. Parikh, MD
Assistant Professor
Department of Neurology
University of Maryland School of Medicine
Associate Medical Director
Division of NeuroCritical Care and Emergency Neurology
University of Maryland Medical Center and R Adams Cowley Shock Trauma Center
Baltimore, Maryland

Marc C. Patterson, MD
Professor
Departments of Neurology, Pediatrics, and Medical Genetics
Mayo Clinic
Consultant
Departments of Neurology, Pediatrics, and Medical Genetics
Mayo Clinic Hospital
Rochester, Minnesota

Siddharama Pawate, MD
Associate Professor of Neurology
Department of Neurology
Vanderbilt University Medical Center
Nashville, Tennessee

Toni S. Pearson, MBBS
Associate Professor
Department of Neurology
Washington University School of Medicine
Attending Neurologist
Department of Neurology
St. Louis Children's Hospital
St. Louis, Missouri

Jonathan Perk, MD, PhD
Residency Program Director
Department of Neurology
SUNY Downstate Medical Center
Brooklyn, New York

Chiara Pisciotta, MD, PhD
Neurologist
Department of Neurology – Carver College of Medicine
University of Iowa Hospitals and Clinics
Iowa City, Iowa

Sean J. Pittock, MD
Professor of Neurology
Departments of Neurology and Laboratory Medicine and Pathology
Consultant
Departments of Neurology and Laboratory Medicine and Pathology
Mayo Clinic
Rochester, Minnesota

Prashanth S. Ramachandran, MBBS
Assistant Professor, Neurology
UCSF Weill Institute for Neurosciences
School of Medicine
San Francisco, California

Ahmad Riad Ramadan, MD
Staff Neurologist
Department of Neurology
Henry Ford Hospital
Detroit, Michigan

Ashwini K. Rao, EdD, OTR, FAOTA
Professor
Rehabilitation & Regenerative Medicine (Programs in Physical Therapy), G.H. Sergievsky Center
Columbia University
New York, New York

Alexandra S. Reynolds, MD
Assistant Professor
Departments of Neurosurgery and Neurology
Icahn School of Medicine at Mount Sinai
New York, New York

Cássia Righy, MD, PhD
Associate Researcher
Laboratory of Intensive Care Medicine
Oswaldo Cruz Foundation
Assistant Physician
Intensive Care Medicine
Paulo Niemeyer Brain's Institute
Rio de Janeiro, Brazil

Claire S. Riley, MD
Assistant Professor of Neurology
Medical Director, Columbia University Multiple Sclerosis Center
Department of Neurology
Columbia University Irving Medical Center
New York, New York

Alden Doerner Rinaldi, MD
Lecturer
Department of Internal Medicine
Harvard Medical School
Boston, Massachusetts
Staff Physician
Care Dimensions
Danvers, Massachusetts

Fred Rincon, MD, MSc, MBEthics
Associate Professor
Department of Critical Care and Neurotrauma
Thomas Jefferson University
Chief, Cerebrovascular Disease
Department of Critical Care and Neurotrauma
Thomas Jefferson University Hospital
Philadelphia, Pennsylvania

Mikael L. Rinne, MD, PhD
Instructor in Neurology
Department of Neurology
Brigham and Women's Hospital, Harvard Medical School
Physician
Center for Neuro-Oncology
Dana-Farber Cancer Institute
Boston, Massachusetts

J. Kirk Roberts, MD
Associate Professor
Department of Neurology
Columbia University
Associate Attending
Department of Neurology
NewYork-Presbyterian Hospital
New York, New York

David J. Roh, MD
Assistant Professor
Department of Neurology
Columbia University
Attending Neurointensivist
Department of Neurology
NewYork-Presbyterian/Columbia University Irving Medical Center
New York, New York

Gustavo C. Román, MD, DrHC
Professor of Neurology
Houston Neurological Institute
Weill Cornell University
New York, New York
Houston Methodist Hospital
Department of Neurology
Texas A&M
Houston, Texas

Karen L. Roos, MD
John and Nancy Nelson Professor of Neurology, Neurology Residency Program Director
Department of Neurology
Indiana University School of Medicine
Indianapolis, Indiana

Roger N. Rosenberg, MD
Zale Distinguished Chair and Professor of Neurology
Department of Neurology
University of Texas Southwestern Medical Center
Attending Neurologist
Department of Neurology
Clements University Hospital
Dallas, Texas

Sara K. Rostanski, MD
Assistant Professor of Neurology
New York University School of Medicine
Medical Director of Stroke
Bellevue Hospital Center

Tatjana Rundek, MD, PhD
Professor of Neurology, Director
Department of Neurology
University of Miami Miller School of Medicine
Miami, Florida

Dimah N. Saade, MD
Neuromuscular and Neurogenetic Disorders of Childhood Section
National Institute of Neurological Disorders and Stroke
National Institutes of Health
Bethesda, Maryland

Ned Sacktor, MD
Professor
Department of Neurology
Johns Hopkins University School of Medicine
Professor
Department of Neurology
Johns Hopkins Bayview Medical Center
Baltimore, Maryland

Daniel H. Sahlein, MD
Partner
Department of Interventional Neuroradiology
Goodman Campbell Brain and Spine
NIR Director of Stroke
Department of Neurointerventional Radiology
Ascension St. Vincent Hospital - Indianapolis
Indianapolis, Indiana

Ramandeep Sahni, MD
Associate Professor of Neurology
Department of Neurology
New York Medical College
Stroke Director
Department of Neurology
Westchester Medical Center
Valhalla, New York

Arash Salardini, MBBS
Associate Professor
Department of Neurology
UT Health San Antonio and Bigg's Institute for Alzheimer's Disease and Neurodegeneration
Associate Professor
Department of Neurology
University Hospital
San Antonio, Texas

Jacinda B. Sampson, MD, PhD
Professor
Department of Neurology
Stanford University
Palo Alto, California

Sophie Samuel, PharmD, BCPS, BCCCP
Critical Care Clinical Specialist
Department of Pharmacy
Memorial Hermann Hospital
Houston, Texas

Tristan T. Sands, MD, PhD
Assistant Professor
Department of Neurology
Columbia University
Attending
Department of Neurology
NewYork-Presbyterian Hospital
New York, New York

Deanna Saylor, MD, MHS
Assistant Professor of Neurology
Department of Neurology
Johns Hopkins University School of Medicine
Neurology Faculty
Department of Neurology
Johns Hopkins Hospital
Baltimore, Maryland

Nikolaos Scarmeas, MD, MS, PhD
Associate Professor
Department of Neurology
Columbia University
New York, New York

Sara M. Schaefer, MD, MHS
Assistant Professor of Neurology
Department of Neurology
Yale School of Medicine
Faculty
Department of Neurology
Yale New Haven Hospital
New Haven, Connecticut

Heidi Schambra, MD
Assistant Professor
Departments of Neurology and Rehabilitation Medicine
New York University Grossman School of Medicine
Division Director of Neuro-Epidemiology
Department of Neurology
NYU Langone Health
New York, New York

David Schiff, MD
Harrison Distinguished Professor
Division of Neuro-Oncology, Department of Neurology
University of Virginia
Co-Director, Neuro-Oncology Center
Division of Neuro-Oncology, Department of Neurology
University of Virginia Health System
Charlottesville, Virginia

Franklin R. Schneier, MD
Special Lecturer
Department of Psychiatry
Columbia University
Co-Director
Anxiety Disorders Clinic
New York State Psychiatric Institute
New York, New York

David B. Seder, MD
Associate Professor
Department of Medicine
Tufts University
Boston Massachusetts
Chair
Critical Care Services
Maine Medical Center
Portland, Maine

Laurent Servais, MD, PhD
Professor of Paediatric Neuromuscular Diseases
MDUK Oxford Neuromuscular Center
Department of Paediatrics
University of Oxford
Oxford, United Kingdom

Jennifer L. Sevush-Garcy, MD
Clinical Associate Professor of Neurology
Department of Neurology
New York Medical College
Valhalla, New York
Attending Neurologist
Department of Neurology
Northern Westchester Hospital
Mount Kisco, New York

Hiral Shah, MD
Assistant Professor
Department of Neurology
Columbia University
Assistant Professor
Department of Neurology
NewYork-Presbyterian Hospital
New York, New York

Vikram G. Shakkottai, MD, PhD
Associate Professor
Department of Neurology
University of Michigan
Director, Ataxia Clinic
Department of Neurology
Michigan Medicine
Ann Arbor, Michigan

Kumud Sharma, MD
Physician Fellow
Department of Neurocritical Care and Neurotrauma
Thomas Jefferson University
Physician Fellow
Department of Neurocritical Care and Neurotrauma
Thomas Jefferson University Hospital
Philadelphia, Pennsylvania

Tarek Sharshar, MD, PhD
Professor
Neuro-anesthesiology and Intensive Care Medicine
GHU-Paris Psychiatrie et Neurosciences
Université de Paris
Paris, France

Tina T. Shih, MD
Clinical Professor of Neurology
Department of Neurology, UCSF Epilepsy Center
University of California, San Francisco
Medical Director
UCSF Neurodiagnostic Lab
UCSF Medical Center
San Francisco, California

Jeffrey Shije, MD
Assistant Professor
Department of Neurology, Neuromuscular Division
University of Florida, Jacksonville
Jacksonville, Florida

Neil A. Shneider, MD, PhD
Claire Tow Associate Professor of Motor Neuron Disorders
Director, Eleanor and Lou Gehrig ALS Center
Department of Neurology
Columbia University
Attending Physician
Department of Neurology
NewYork-Presbyterian Hospital
New York, New York

Priya Shoor, MD
Attending Radiologist
Department of Radiology, Emergency Division
Columbia University Irving Medical Center
New York, New York

Michael E. Shy, MD
Professor of Neurology
Department of Neurology – Carver College of Medicine
University of Iowa
Director of the Division of Neuromuscular Medicine, Director of the Division of Neurogenetics
Department of Neurology – Carver College of Medicine
University of Iowa Hospitals and Clinics
Iowa City, Iowa

Reet Sidhu, MD
Assistant Professor of Pediatrics
Division of Pediatric Neurology
Emory University
Director, Developmental Neurology Program
Department of Pediatric Neurology
Children's Healthcare of Atlanta
Atlanta, Georgia

Harvey S. Singer, MD
Professor Emeritus
Department of Neurology
Johns Hopkins University
Staff
Department of Neurology
Kennedy Krieger Institute/Johns Hopkins Medicine
Baltimore, Maryland

Michael B. Sisti, MD, FACS
James G. McMurtry III MD Associate Professor of Neurology
Department of Neurology
Columbia University
Attending Neurosurgeon and Co-Director Center for Radiosurgery
Department of Neurosurgery
NewYork-Presbyterian Hospital
New York, New York

Robert A. Solomon, MD
Chairman Emeritus
Bennett M. Stein Professor of Neurological Surgery
Columbia University
NewYork-Presbyterian Hospital
New York, New York

Serena Spudich, MD, MA
Gilbert H. Glaser Professor and Chief, Division of Neurological Infections and Global Neurology
Department of Neurology
Yale School of Medicine
New Haven, Connecticut

Shraddha Srinivasan, MD
Assistant Professor of Neurology
Department of Neurology
Columbia University Irving Medical Center
Attending Physician
Department of Neurology
NewYork-Presbyterian Hospital
New York, New York

Joel Stein, MD
Simon Baruch Professor
Department of Rehabilitation and Regenerative Medicine
Columbia University
Chief
Department of Rehabilitation Medicine
NewYork-Presbyterian Hospital
New York, New York

Barney J. Stern, MD
Professor
Department of Neurology
Johns Hopkins University
Baltimore, Maryland

Yaakov Stern, PhD
Florence Irving Professor of Neuropsychology
Department of Neurology
Columbia University
Chief
Cognitive Neuroscience Division, Department of Neurology
Columbia University Irving Medical Center
New York, New York

Ian S. Storper, MD
Director, Otology Program
Northwell Physician Partners
Otolaryngology Lenox Hill Hospital
Department of Otolaryngology
Lenox Hill Hospital
New York, New York

T. Scott Stroup, MD, MPH
Professor
Department of Psychiatry
Columbia University
Research Psychiatrist
New York State Psychiatric Institute
New York, New York

Sally M. Sultan, MD, MS
Instructor of Pediatrics at CUIMC
Division of Pediatrics CAH, Department of Pediatrics
NewYork-Presbyterian Hospital
New York, New York

Kurenai Tanji, MD, PhD
Professor
Department of Pathology and Cell Biology
Columbia University
Attending Neuropathologist
Department of Pathology and Cell Biology
NewYork-Presbyterian Hospital
New York, New York

Claudio E. Tatsui, MD
Associate Professor
Department of Neurosurgery
UT MD Anderson Cancer Center
Houston, Texas

Boon Lead Tee, MD, MSc
Assistant Professor
Department of Neurology
University of California, San Francisco
San Francisco, California
Attending Physician
Department of Neurology
Buddhist Tzu Chi Hospital
Hualien, Taiwan

Pichet Termsarasab, MD
Consultant Neurologist
Division of Neurology, Department of Medicine
Faculty of Medicine Ramathibodi Hospital, Mahidol University
Bangkok, Thailand

Kiran T. Thakur, MD
Winifred Mercer Pitkin Assistant Professor of Neurology
Department of Neurology
Columbia University Irving Medical Center
Assistant Professor
Department of Neurology
NewYork-Presbyterian Hospital
New York, New York

Rebecca Traub, MD
Assistant Professor
Department of Neurology
University of North Carolina, Chapel Hill
Chapel Hill, North Carolina

Spyridoula Tsetsou, MD
Assistant Professor
Department of Neurosurgery
Icahn School of Medicine at Mount Sinai
New York, New York

Christina M. Ulane, MD, PhD
Assistant Professor of Neurology
Department of Neurology, Division of Neuromuscular Medicine
Columbia University Irving Medical Center/NewYork-Presbyterian Hospital
New York, New York

Julio R. Vieira, MD, MS
Assistant Professor of Neurology
Department of Neurology
Albert Einstein College of Medicine
Bronx, New York

Tobias Walbert, MD, MPH
Associate Professor
Department of Neurology
Wayne State University
Co-Director Hermelin Brain Tumor Center
Department of Neurology & Neurosurgery
Henry Ford Hospital
Detroit, Michigan

Ruth H. Walker, MB, ChB, PhD
Professor
Department of Neurology
Mount Sinai School of Medicine
New York, New York
Director, Movement Disorders Clinic
Department of Neurology
James J. Peters Veterans Affairs Medical Center
Bronx, New York

Natalie Weathered, MD, MS
Assistant Professor of Neurology
Department of Neurology
Weill Cornell Medicine
Assistant Attending of Neurology
Department of Neurology
NewYork-Presbyterian Hospital
New York, New York

Louis H. Weimer, MD
Professor of Neurology at the Columbia University Medical Center
Department of Neurology
Columbia University Vagelos College of Physicians and Surgeons
Associate Attending
Department of Neurology
NewYork-Presbyterian Hospital
New York, New York

Michael L. Weinberger, MD
Associate Professor of Anesthesiology
Columbia University Irving Medical Center
New York, New York

Brian G. Weinshenker, MD
Professor
Department of Neurology
Mayo Clinic
Consultant
Department of Neurology
Mayo Clinic
Rochester, Minnesota

Patrick Y. Wen, MD
Professor of Neurology
Harvard Medical School
Director, Center For Neuro-oncology
Medical Oncology
Dana-Farber Cancer Institute
Boston, Massachusetts

Sarah F. Wesley, MD, MPH
Assistant Professor
Department of Neurology
Yale University School of Medicine
New Haven, Connecticut

Andrew J. Westwood, MD, FRCP(Edin)
Assistant Professor
Department of Neurology
Columbia University
Attending
Department of Neurology
NewYork-Presbyterian – Columbia Campus
New York, New York

Eelco F. M. Wijdicks, MD, PhD
Professor of Neurology
Division of Neurocritical Care and Hospital Neurology
Mayo Clinic
Rochester, Minnesota

Joshua Z. Willey, MD, MS
Associate Professor
Department of Neurology
Columbia University Irving Medical Center
Attending
Department of Neurology
NewYork-Presbyterian Hospital
New York, New York

Michael R. Wilson, MD, MAS
Associate Professor
Department of Neurology
University of California, San Francisco
Attending Neurologist
Department of Neurology
University of California, San Francisco Medical Center and Zuckerberg San Francisco General Hospital
San Francisco, California

Christopher J. Winfree, MD, FAANS
Assistant Professor
Department of Neurological Surgery
Columbia University
New York, New York

Scott M. Woolf, DO
Neurology Resident
Department of Neurology
Westchester Medical Center
Chief
Department of Neurology
Westchester Medical Center
Valhalla, New York

Anne Damian Yacoub, MD
Assistant Professor
Department of Neurology
Johns Hopkins School of Medicine
Clinical Associate
Department of Neurology
Johns Hopkins Hospital
Baltimore, Maryland

Christopher Zammit, MD, FACEP
Adjunct Assistant Professor
Emergency Medicine, Neurology, and Neurosurgery
University of Rochester School of Medicine & Dentistry
Rochester, New York
Medical Director, Stroke, Neurologic Emergencies, and Neurosciences ICU
Department of Neurosciences and Critical Care
Good Samaritan Hospital, TriHealth Hospital System
Cincinnati, Ohio

Anastasia Zekeridou, MD, PhD
Assistant Professor
Department of Neurology and Laboratory Medicine and Pathology
Mayo Clinic
Rochester, Minnesota

Joseph R. Zunt, MD, MPH
Professor
Department of Neurology, Global Health, Medicine (Infectious Diseases), Epidemiology
University of Washington
Professor
Harborview Medical Center
Seattle, Washington

Contents

SECTION I

GLOBAL BURDEN OF NEUROLOGIC DISEASE 1

Section Editor: *Mitchell S. V. Elkind*

1 Worldwide Epidemiology of Neurologic Disease 1
Jennifer Sevush-Garcy and Mitchell S. V. Elkind

2 Global Delivery of Neurologic Care 9
Hiral Shah, Serena Spudich, and Kiran T. Thakur

SECTION II

APPROACH TO THE NEUROLOGIC PATIENT 15

Section Editor: *James M. Noble*

3 Neurologic History Taking, Localization, and Differential Diagnosis 15
James M. Noble

4 The Neurologic Examination 25
James M. Noble

SECTION III

COMMON PROBLEMS IN NEUROLOGY 45

Section Editor: *J. Kirk Roberts*

5 Dizziness, Vertigo, and Hearing Loss 45
J. Kirk Roberts

6 Syncope 51
Tina T. Shih

7 Seizures 57
Michelle Bell, David J. Roh, and Jan Claassen

8 Pain, Numbness, and Paresthesias 64
Comana M. Cioroiu

9 Headache and Facial Pain 70
Ashhar S. Ali and Julio R. Vieira

10 Visual Disturbances 77
Heather E. Moss

11 Delirium 88
Merrick E. Miles, Christina J. Hayhurst, and Christopher G. Hughes

12 Dementia and Memory Loss 95
Lawrence S. Honig and James M. Noble

13 Involuntary Movements 103
Sara M. Schaefer and Elan D. Louis

14 Muscle Weakness, Cramps, and Stiffness 110
Comana M. Cioroiu

15 Gait Disorders 122
Ashwini K. Rao

16 Acute Stroke: The First Hour 132
Barry M. Czeisler and Stephan A. Mayer

17 Acute Spinal Cord Syndromes 145
Natalie Weathered and Noam Y. Harel

18 Focal Mass Lesions 152
Michelle Bell, Alexander G. Khandji, and Fabio M. Iwamoto

19 Stupor and Coma 168
Jan Claassen and John C. M. Brust

20 Brain Death 179
Eelco F. M. Wijdicks

SECTION IV

DIAGNOSTIC TESTS 184

Section Editor: *James M. Noble*

21 Computed Tomography 184
Priya Shoor, Daniel S. Chow, and Angela Lignelli

22 Magnetic Resonance Imaging 189
Eric Newman and Angela Lignelli

23 Positron Emission Tomography and Single-Photon Emission Computed Tomography 203
William Charles Kreisl

24 Neurovascular Ultrasound 208
Tatjana Rundek

25 Angiography and Neuroendovascular Surgery 217
Katarina Dakay, Scott M. Woolf, Gurmeen Kaur, Daniel H. Sahlein, and Fawaz Al-Mufti

26 Electroencephalography and Evoked Potentials 230
Nicolas Gaspard and Emily J. Gilmore

27 Electromyography, Nerve Conduction Studies, and Magnetic Stimulation 243
Louis H. Weimer

28 Autonomic Testing 255
Louis H. Weimer

29 Evaluation of the Special Senses (Vision, Hearing, Smell, Vestibular System) 259
J. Kirk Roberts

30 Sleep Studies 264
Andrew J. Westwood and Carl W. Bazil

31 Neuropsychological Evaluation 271
Yaakov Stern

32 Lumbar Puncture and Cerebrospinal Fluid Analysis 277
Kiwon Lee

33 Brain, Muscle, Nerve, and Skin Biopsy 283
John F. Crary, Thomas H. Brannagan III, and Kurenai Tanji

34 Intracranial Pressure and Neurocritical Care Monitoring 288
Charles L. Francoeur and Stephan A. Mayer

35 Genetic Testing and DNA Diagnosis 297
Jill S. Goldman and Jacinda B. Sampson

SECTION V

CEREBROVASCULAR DISEASES 301
Section Editor: *Stephan A. Mayer*

36 Acute Ischemic Stroke 301
Charles C. Esenwa and Stephan A. Mayer

37 Transient Ischemic Attack 320
Setareh Salehi Omran and Jose Gutierrez

38 Hypoxic-Ischemic Encephalopathy 324
Sachin Agarwal and Alexandra S. Reynolds

39 Intracerebral Hemorrhage 332
Stephan A. Mayer and Fred Rincon

40 Subarachnoid Hemorrhage 342
Stephan A. Mayer, Gary L. Bernardini, and Robert A. Solomon

41 Cerebral Venous and Sinus Thrombosis 353
Jennifer A. Frontera and Natalie Organek

42 Vascular Malformations 361
Fawaz Al-Mufti and Stephan A. Mayer

43 Central Nervous System Vasculitis 370
Kavneet Kaur, Hussein Alshammari, Ramandeep Sahni, Steven Marks, Stephan A. Mayer, and Fawaz Al-Mufti

44 Posterior Reversible Encephalopathy Syndrome and Other Cerebrovascular Syndromes 384
Claire S. Riley, Sara K. Rostanski, and Joshua Z. Willey

45 Primary and Secondary Stroke Prevention 401
Charles C. Esenwa and Mitchell S. V. Elkind

SECTION VI

NEUROTRAUMA 413
Section Editor: *Neeraj Badjatia*

46 Concussion and Chronic Traumatic Encephalopathy 413
James M. Noble and John F. Crary

47 Traumatic Brain Injury 420
Gunjan Y. Parikh, Neeraj Badjatia, and Stephan A. Mayer

48 Traumatic Spinal Cord Injury 441
Christopher E. Mandigo, Michael G. Kaiser, and Peter D. Angevine

49 Traumatic Cranial and Peripheral Nerve Injury 451
Dominique M. O. Higgins, Lillian Liao, and Christopher J. Winfree

SECTION VII

DEMENTIA 469
Section Editor: *Karen S. Marder*

50 Mild Cognitive Impairment 469
Lawrence S. Honig, Arash Salardini, William Charles Kreisl, and James M. Noble

51 Alzheimer Disease 476
Lawrence S. Honig and James M. Noble

Videos

The following videos can be found in the companion e-book edition.

Chapter 13: Involuntary Movements

Video 13.1. Myoclonus involving the left arm.

Video 13.2. Torticollis.

Video 13.3. Chorea in two twins with Huntington disease.

Video 13.4. Facial tics.

Video 13.5. Kinetic tremor during spiral drawing in a patient with essential tremor.

Video 13.6. Akathitic movements in a patient exposed to antipsychotic drug therapy.

Video 13.7. Patient with Parkinson disease exhibits dyskinesias, especially in his legs but also in his arms.

Chapter 60: Classification of Seizures and Epilepsy

Video 60.1. Generalized tonic-clonic seizure. Abrupt vocalization with tonic posturing of both arms and legs followed by symmetric clonic jerking of all four extremities and face, followed by stertorous breathing in the postictal phase.

Video 60.2. Atonic seizure. Sudden loss of tone during activity causing head and arm drop.

Video 60.3. Automatisms in a right temporal lobe seizure. Ictal speech followed by right hand automatisms (sign of the cross with right hand, stereotyped stroking movements with right hand).

Video 60.4. Frontal lobe seizure with bizarre semiology. Bicycling movements of both legs occurring out of sleep, bizarre vocalizations, and facial grimacing followed by a very brief postictal state with rapid return to baseline mental status.

Video 60.5. Epilepsia partialis continua (EPC). Rhythmic twitching of the left face and mouth.

Chapter 61: Management of Epilepsy

Video 61.1. Psychogenic nonepileptic seizure. Waxing and waning arrhythmic and asynchronous arm and leg movements with side-to-side head movements and pelvic thrusting.

Chapter 74: Autoimmune Encephalitis and Meningitis

Video 74.1. Male patient with opsoclonus-myoclonus syndrome, immunotherapy responsive. (From Klaas JP, Ahlskog JE, Pittock SJ, et al. Adult-onset opsoclonus-myoclonus syndrome. *Arch Neurol*. 2012;69:1598-1607.)

Video 74.2. Male patient with subacute onset chorea and behavioral change. Contactin-associated protein 2 (CASPR2) autoimmunity detected, Huntington disease genetic testing negative. (From O'Toole O, Lennon VA, Ahlskog JE, et al. Autoimmune chorea in adults. *Neurology*. 2013;80[12]:1133-1144.)

Video 74.3. Male patient with faciobrachial dystonic seizures in the context of leucine-rich glioma–inactivated protein 1 (LGI1) encephalitis.

Video 74.4. Two female patients with brainstem encephalitis in the context of antineuronal nuclear antibody type 2 (ANNA-2) (anti-Ri) autoimmunity and breast adenocarcinoma. Note the eye movement abnormalities, exaggerated startle, postural instability, axial rigidity, and jaw dystonia. (From Pittock SJ, Parisi JE, McKeon A, et al. Paraneoplastic jaw dystonia and laryngospasm with antineuronal nuclear autoantibody type 2 [anti-Ri]. *Arch Neurol*. 2010;67[9]:1109-1115.)

Video 74.5. A female patient with stiff person syndrome. Note the nonreducing lumbar lordosis and stiff-legged gait.

Chapter 76: Essential Tremor

Video 76.1. A kinetic tremor is apparent as this patient with essential tremor (ET) draws a spiral.

Video 76.2. In approximately 50% of essential tremor (ET) patients, the tremor has an intentional component, worsening on finger-nose-finger maneuver as the patient approaches one or both of the two targets.

Chapter 80: Hemifacial Spasm

Video 80.1. Patient with hemifacial spasm. She has spasms of the orbicularis oculi, zygomaticus major, depressor anguli oris, and other muscles innervated by the facial nerve. Contractions in all muscles seem to be simultaneous. She has individual twitches, trains of twitches, and trains of twitches rapid enough to cause sustained partial eyelid closure and sustained pulling of the corner of the mouth. Contractions are triggered by looking up as well as many other actions controlled by the facial nerve not shown in this video. One may also see contractions of the platysma, depressors of the corner of the mouth, mentalis contractions that cross the midline), and of the upper lip.

Chapter 81: Myoclonus

Video 81.1. Myoclonus in Rasmussen encephalitis. This video demonstrates epilepsia partialis continua seen as myoclonic movements of the left orbicularis oculi with tonic contraction on the left lower face. These were much improved after intravenous immunoglobulin (IVIG) treatment.

Video 81.2. Posthypoxic myoclonus. The patient had generalized synchronous large-amplitude myoclonic jerks, more prominent with action than at rest. When standing, there was negative myoclonus of bilateral lower extremities, giving "a bouncing gait."

Video 81.3. Myoclonus-dystonia syndrome. The patient had myoclonic jerks, more prominent in proximal regions including neck, bilateral shoulders, and proximal upper extremities. Myoclonus was obvious with action including writing and pouring water from a cup but also occurred intermittently at rest.

Video 81.4. Hyperekplexia. This baby had severe exaggerated startle. Synchronous generalized myoclonic jerks of all extremities, upper greater than lower, were present even at rest and were also elicited by tapping the nose. Note that we do not recommend performing the repetitive nose tapping shown in this video. The latter part of the video shows hyperekplexia in Poll Hereford cattle. There were generalized myoclonic jerks with somesthetic stimuli.

Video 81.5. Propriospinal myoclonus. This video demonstrates reflex myoclonus, axial jerks shown as truncal flexion after being tapped with a reflex hammer. Note the relatively long latency between the taps and truncal flexion due to slow conduction via propriospinal pathways, in contrast to the short latency in cortical myoclonus due to conduction through corticospinal pathways.

Chapter 82: Hereditary and Acquired Ataxias

Video 82.1. Neurological exams of ataxia in a case of spinocerebellar ataxia type 1 (SCA1). This individual has variable stride length and walking directions. She has increased body sway in standing and also difficulty in tandem stance. While sitting, she has mild truncal sways and slurred speech while talking. She has overshoot in her finger chase exam and intention tremor in her finger-nose exam. She has slow rapid alternating movements. In the heel-shin slide exam, her heel falls off her shin several times.

Video 82.2. Gait progression in ataxia patients. An example of mild ataxia with turning difficulty in a case of spinocerebellar ataxia type 1 (SCA1) (segment 1). Another sign of mild ataxia is variable stride length and different walking directions as exemplified in a patient with POLG ataxia (segment 2). As the ataxia progresses, a slight wide-based gait develops, illustrated in a patient with spinocerebellar ataxia type 6 (SCA6) (segment 3). Finally, when ataxia becomes more severe, a marked wide-based gait becomes evident to compensate for the deficits, demonstrated in a patient with spinocerebellar ataxia type 35 (SCA35). The patient still have variable stride length and direction of walking, in addition to a wide-based gait (segment 4).

Video 82.3. Eye movement abnormalities in cerebellar ataxia. End-gaze nystagmus in POLG ataxia (segment 1). Slow saccades in spinocerebellar ataxia type 2 (SCA2) (segment 2). Hypermetric saccades in spinocerebellar ataxia type 1 (SCA1) (segment 3). Hypometric saccades in multiple system atrophy, cerebellar type (segment 4). Impaired vertical saccades with relatively preserved horizontal saccades in Niemann-Pick type C (segment 5).

Video 82.4. A spinocerebellar ataxia type 2 (SCA2) patient exhibits dysarthria, slow saccades, dysmetria in the finger-chin test, impaired rapid alternating movements, overshoot in the finger chase exam, hyporeflexia, a wide-based gait with variable walking directions.

Video 82.5. A spinocerebellar ataxia type 7 (SCA7) patient demonstrates dysarthria, impaired vision acuity, severe dysmetria on the finger-nose exam, severe overshoot on the finger chase exam, and severe dysmetria on heel-shin slides.

Video 82.6. A case of multiple system atrophy, cerebellar type shows hypomimic facial expression, bradykinesia on the hand open/close exam, hand pronation/supination exam, finger taps, and foot taps, worse on the left side than the right side. He also has overshoot in the finger chase exam, abnormal rapid alternating movements, and hyperreflexia. During walking, he has difficulty in turning, loss of left arm swing, dragging his left foot, in addition to cerebellar ataxia.

Chapter 83: Tardive Dyskinesia and Other Neuroleptic-Induced Syndromes

Video 83.1. Oculogyric crisis and drug-induced parkinsonism. A teenage girl developed drug-induced parkinsonism and oculogyric crisis on antipsychotic medication. She has intermittent involuntary eye deviation upward as well as hypomimia, bradykinesia, and tremor.

Video 83.2. Classic orobuccolingual dyskinesia and limb dyskinesia. The patient has typical orobuccolingual movements resembling chewing and swallowing as well as tongue popping and lip puckering. Oral movements cease when she talks and does not interfere with speech significantly. She also shows repetitive finger extension and flexion. The right thumb is in extended position, suggesting a dystonic component. She has similar flexion and extension movement of toes and wrist, when standing up.

Video 83.3. Tardive dystonia. The patient shows excessive eye blinking and closure (blepharospasm) as well as lower facial grimacing movement. Her eyes open better when talking than listening to examiner.

Video 83.4. Tardive akathisia. The patent has flexion and extension and rotation of ankles, which makes her look restless. She can suppress the movements partially for several seconds and describes her "need" to move.

Chapter 84: Choreas

Video 84.1. Sydenham disease. A 13-year-old boy with a 2-month history of left hemichorea and prior history of sore throat; serum antistreptolysin O (ASO) titer is greater than 600. The chorea completely resolved in 6 months.

Video 84.2. Kernicterus. An 11-year-old boy with a history of marked and prolonged neonatal jaundice, delayed developmental milestones, generalized choreoathetosis, vertical ophthalmoparesis, and deafness, typical of kernicterus.

Chapter 85: Huntington Disease

Video 85.1. Motor signs of Huntington disease.

Chapter 86: Parkinson Disease

Video 86.1. Rest tremor. The right arm tremor subsides briefly as the arm moves from resting to an outstretched position where it subsequently re-emerges. In the left arm, tremor continues from rest to kinetic and to posture-maintenance positions. No kinetic tremor is seen with the right arm during finger-to-nose maneuver, though the left arm shows some. There is jaw tremor at rest. While walking, the patient exhibits rest tremor in both arms.

Video 86.2. Typical Parkinsonian features (bradykinesia and gait disturbance). The patient exhibits mildly slurred speech and decreased facial expression with diminished blinking and a partially opened mouth. She also has mild oral dyskinesia. Rapid alternating movements are impaired bilaterally, more on the left. Finger tapping is slow, irregular, and small in amplitude; it is also more impaired on the left. The patient arises using a push against the arm rest. Her posture is mildly forward-flexed. Though she takes full strides with a normal base, her gait lacks heel strikes and there is bilateral decreased arm swing. She requires five steps to complete a 180-degree turn. In response to the pull test, she takes four steps of retropulsion before her backward fall was caught by the examiner.

Video 86.3. Levodopa-induced dyskinesia. The patient exhibits truncal, oral, and arm dyskinesia. There is also dystonic posturing of the left arm, activated by voluntary movement of the right arm. During walking, she shows excessive swinging of the left arm and oral dyskinesia is activated. The patient fails to regain balance on the pull test. Parkinsonian symptoms (left-sided rest tremor and bradykinesia) re-emerge a

few minutes after the overtly dyskinetic state (though oral dyskinesia persists).

Video 86.4. Freezing of gait. The patient freezes after reaching a destination and making a turn. While attempting to re-start walking, he develops tremulous movements in the legs. After a few seconds, he is able to resume his gait.

Chapter 87: Parkinson-Plus Syndromes

Video 87.1. Patient with mild signs and symptoms of progressive supranuclear palsy (PSP) for 2 years. Continuous, tiny square wave jerks are visible when he fixates. He has extremely limited upgaze and downgaze. He does not generate saccades when asked to look left or right. He is able to open his eyes after lid closure, but there is a delay on the left. Tongue movements are mildly slow. He has marked axial bradykinesia (slowed shoulder shrug on the right) with mild slowing of rapid succession movements of the hands or feet. His blink rate is markedly reduced, and he has a stare. He is able to rise from a chair with arms crossed, although slowly. He has a mildly broad-based, slow gait with right greater than left arm abduction ("gunslinger's walk") and decreased arm swing.

Video 87.2. Patient with more severe progressive supranuclear palsy (PSP). She has the characteristic facial dystonia of PSP producing a troubled or angry look. She has poor balance, cannot rise from a chair safely with arms crossed, and falls in all directions. She also has a mildly broad-based stance and gait. When instructed to step backward when pulled from behind, she falls backward.

Video 87.3. Patient seen initially with mild signs and symptoms of cortical-basal ganglionic degeneration (CBGD). She has dystonic posturing of the right hand with twisting, slightly jerky movements of the right forearm, wrist, and fingers. Rapid succession movements of the upper extremities are mildly slowed on the left and markedly slowed on the right. She can rise slowly from a chair using her left hand. Her gait is slow, with mildly broad-based, short stride on the left, dystonic posturing of both arm and leg on the right with even shorter stride, and no heel strike on either side. She turns en bloc, barely lifting the right foot. Two years later, she spends almost all her time in a wheelchair. She has severe dystonic posturing of the right arm and hand. She has overflow elevation of the right arm and left leg when she lifts the left. She has almost no function of the right hand or arm, requiring the left for simple actions like raising or lowering the arm. The left side is slow but significantly more functional than the right. She needs assistance to rise from a chair, and when she does, her right leg elevates and she can barely lower it to the ground and cannot support her weight with her legs alone.

Chapter 107: Spinal Tumors

Video 107.1. Gross total resection of the thoracic meningioma seen in Figure 107.6. After standard posterior thoracic laminectomy and midline opening of the dura mater is completed, microsurgical technique is used to dissect the arachnoid plane and separate the tumor from the spinal cord, nerve roots, and radiculomedullary artery and veins. Subsequently, the tumor capsule is incised, and a debulking followed by piecemeal resection is performed. After gross total resection is achieved, the dural insertion is cauterized to reduce risk of recurrence. We opted not to remove the dura given the anterior location and potential morbidity of a cerebrospinal fluid (CSF) leak.

Video 107.2. Gross total resection of an intramedullary ependymoma. After standard posterior thoracic laminectomy and midline opening of the dura mater is completed, microsurgical technique is used to perform a midline posterior myelotomy at the level of the posterior midline sulcus. The myelotomy is extended to allow complete exposure of the tumor. A plane of cleavage is developed and the dorsal and lateral border of the mass are gently separated from the surrounding spinal cord. Subsequently, the tumor is mobilized away from the ventral columns, and all feeders from the anterior spinal artery are cauterized and cut allowing en bloc resection of the ependymoma.

Chapter 119: Heart-Brain Interactions

Video 119.1. Typical takotsubo.

Video 119.2. Atypical takotsubo.

Worldwide Epidemiology of Neurologic Disease

1

Jennifer Sevush-Garcy and Mitchell S. V. Elkind

KEY POINTS

1. Assessing burden of neurologic disease requires measurement of both disease mortality and morbidity (disability, handicap, etc.).
2. The disability-adjusted life year (DALY) is a metric that combines years of life lost due to premature death and years of healthy life lost as a result of disability, weighted by the severity of the disability.
3. Neurologic disorders account for the largest proportion of DALYs of any category of disease.
4. The *double burden* of disease refers to the phenomenon whereby developing countries experience the adverse consequences of a modern lifestyle before escaping the problems of poverty, which helps to explain why countries in the middle levels of development have the highest rates of some neurologic disorders such as stroke.
5. Stroke incidence has increased in low- and middle-income countries, whereas high-income countries have experienced a 42% decrease in incidence over the past four decades.
6. Limitations in neurologic resources and variability in resource allocation to neurologic problems contribute to disparities in the global burden of neurologic disease as well as local variations within nations.

INTRODUCTION

Neurologic disorders are globally among the most important causes of human illness and mortality. Quantifying the burden of neurologic disease and its impact on populations throughout the world is challenging for several reasons, however. First, neurologic disease includes disorders that primarily affect the brain as well as diseases that affect other body systems but have prominent neurologic manifestations. Second, neurologic diseases are notable for more frequently causing disability than death. Commonly used measures of disease impact, such as hospitalization or mortality rates, may not capture the impact of nonfatal neurologic problems such as migraine or epilepsy. Third, there are often disparities in neurologic disorders caused by socioeconomic and geographic factors. Assessment and diagnosis of neurologic disease may also depend on resources available for their measurement that are not available in all environments. Despite these limitations, present estimates of the burden of neurologic disorders suggest that they have an enormous impact on human health.

THE CLASSIFICATION OF DISEASE: WHAT IS A NEUROLOGIC DISORDER?

Neurologic disorders can be broken down into two general categories: primary neurologic disorders affecting the nervous system only and secondary neurologic disorders, in which injury or dysfunction of the nervous system occurs as a result of a disease that primarily affects another organ system or in which dysfunction of the nervous system occurs along with dysfunction of several other organ systems. Examples of primary neurologic disorders include Alzheimer disease, migraine, and multiple sclerosis. Examples of secondary neurologic disorders include seizures secondary to infection with malaria, paraneoplastic syndromes associated with primary systemic cancer, and peripheral neuropathy occurring in the setting of nutritional deficiencies.

The distinction between primary and secondary neurologic disorders complicates the task of estimating global disease burden. For instance, do we classify diabetic neuropathy as a neurologic disorder or as a complication of an endocrinologic disorder? Should stroke be considered a neurologic disorder or a cardiovascular disease? Should head injury in the context of a motor vehicle accident be counted toward the burden of disease of neurologic disorders or of accidents? Various approaches have been taken to answer these questions, and in some instances, the definitions may shift depending on the purpose of the analysis. Although these distinctions may seem academic at first glance, they could have implications for public health campaigns and approaches to measuring, reporting, and acting on the relative burden of illness caused by different diseases.

ESTIMATING DISEASE BURDEN

There are several measures used to evaluate disease burden, including incidence, prevalence, morbidity, case fatality, mortality, disability, quality of life, pain, and cost. Incidence and prevalence are used to determine how common a disease is. The number of first cases of a disease over a defined time interval in a defined population determines its incidence. Prevalence measures the total number of cases, new and old, at a particular time in a defined

population. Both indices depend on the accurate and complete enumeration of cases and adequate knowledge of the underlying population at risk. Case fatality refers to the proportion of patients with a disease who die from it. Mortality refers to the overall number of deaths due to the disease in a given time period.

Mortality

Traditional approaches to estimating the impact of illness have focused on mortality because it is relatively easy to measure. The impact of some neurologic disorders may be reasonably captured by reference to their case fatality or mortality. For example, malignant brain tumors, strokes, and head injuries are often severe and may lead to death. A metric focused exclusively on mortality, however, will fail to capture the impact of many neurologic disorders that are chronic and slowly progressive, or intermittent and disabling, but that do not cause their sufferers to die. For example, multiple sclerosis is a disease process that has low mortality but inflicts a rather high level of disability on its patients; however, it is relatively rare. Alternatively, migraine is a neurologic disorder that also has low mortality but has moderate disability and is extremely common. Clearly, attempts to measure this type of disease burden require a more versatile metric than mortality alone.

Morbidity

More recent attempts to measure disease burden have therefore aimed at capturing not only mortality but also morbidity, which captures the disability, handicap, and other physical costs associated with the disease. One common approach to measuring burden of disease is to consider a time-based metric that incorporates premature mortality (the number of years of life lost due to premature death, based on an expected life span) and disability (years of healthy life lost as a result of disability weighted by the severity of the disability). The combination of both of these measures yields disability-adjusted life years (DALYs). The DALYs are a well-established metric of disease burden that measures the number of healthy years of life lost as a result of both death and disability caused by a particular disease. One DALY constitutes 1 year of healthy life lost in an ideal world in which everyone lives into old age free of any disease or disability. One advantage to using the DALY to measure disease burden is that it allows comparisons of impact across very different disease states, in effect serving as a common measure for acute severe illness (stroke, head injury, myocardial infarction) and less severe chronic illnesses (epilepsy, migraine). The DALY metric thus reflects the impact of disease on both early mortality and on disability, both of which are particularly important for assessing the overall impact of neurologic disease.

Neurologic disorders account for the largest proportion of DALYs of any category of disease, more so than cancer, heart disease, or pulmonary disease (Fig. 1.1). Neurologic disorders are also the second largest group causing global death. Among neurologic disorders, stroke, migraine, meningitis, Alzheimer disease, and epilepsy each caused more than 10 million DALYs. Within the category of neurologic disorders, the greatest proportion of DALYs is due to stroke, which represents just about half of the DALYs due to all neurologic disorders. Alzheimer disease and other dementias, together with meningitis and epilepsy, comprise another quarter of the DALYs seen with neurologic disease. Perhaps surprisingly, migraine encompasses 13.1% of DALYs among neurologic disorders, which is over 10 times that encompassed by Parkinson disease and multiple sclerosis combined, although it contributes little to the occurrence of deaths. Likewise, although epilepsy contributes to almost 5% of DALYs, it is responsible for only 1.3% of deaths. Stroke, on the other hand, which is frequently fatal, is responsible for 67.3% of deaths when compared to other neurologic disorders (Fig. 1.2).

Life Expectancy

Another increasingly used metric of the impact of neurologic disease is Health Adjusted Life Expectancy, or HALE. Life expectancy is the average number of years that a person is expected to live based on current mortality rates in the population. The HALE is life expectancy adjusted for disease and disability. This is the average number of years that person can expect to live in full health, taking into account years lived in less than full health. In order to measure HALE, a measurement is needed of both how many people a disease affects and the impact on health and function of the disease on the people who have it. Combining these two effectively creates a measure of disease-free life expectancy weighted by the severity of the disease.

Estimates from the Global Burden of Disease Study 2015, sponsored by the World Health Organization (WHO), suggested increasing life expectancy in recent years allowed more of the population to reach ages where neurologic diseases become more prevalent. In addition, there has been improvement in risk factor optimization and advances in medical care, such as secondary stroke prevention and acute stroke treatment, that impact the burden of neurologic disorders around the world.

FIGURE 1.2 Contribution of various neurologic disorders to the overall burden from neurologic disorders in 2015. Estimates are for disability-adjusted life-years (A) and deaths (B). (From GBD 2015 Neurological Disorders Collaborator Group. Global, regional, and national burden of neurological disorders during 1990-2015: a systematic analysis for the Global Burden of Disease Study 2015. *Lancet Neurol.* 2017;16[11]:877-897.)

THE SHIFTING CHARACTER OF NEUROLOGIC DISEASE OVER TIME

The relative importance of different neurologic disorders over time has changed not only as a consequence of changes in population demographics and risk factors but also as a consequence of world events and scientific knowledge. For example, tremendous advances in our understanding of peripheral nerve injuries, including phantom limb pain, occurred in the 19th century during the Civil War, through the examination of amputees and injured soldiers by Silas Weir Mitchell and colleagues. Further advances in our understanding of head injuries occurred during the First World War. Early in the 20th century, neurologists also frequently encountered brain injury as a direct or indirect consequence of infections, including syphilis, tuberculosis, and viral encephalitis. For example, the Spanish flu pandemic of 1918 to 1919 gave rise to many cases of postencephalitic parkinsonism, a disorder made familiar to many through Oliver Sacks' *Awakenings*. Later in the century, as life expectancy in developed countries increased, disorders of the elderly, including stroke and neurodegenerative disorders such as Parkinson disease and Alzheimer disease, were commonly encountered. Infectious neurologic disorders resurfaced again, however, in the 1980s in the form of the human immunodeficiency virus (HIV)/AIDS epidemic, with its well-known complications of toxoplasmosis and cerebral lymphoma. Rare and initially mystifying neurologic diseases have also captured the popular imagination and generated interest beyond what would be expected from the numbers of patients affected; the spongiform encephalopathies caused by prions, such as new variant Creutzfeldt-Jakob disease (or mad cow disease), had a tremendous impact in terms of teaching us about how diseases can jump from one species to another.

THE EPIDEMIOLOGIC TRANSITION AND THE DOUBLE BURDEN OF DISEASE

The concept of the "epidemiologic transition" has been used to explain the shift in the types of diseases that often occur in countries as they pass through different stages of development. As nations industrialize and develop, the major causes of death and disability shift from a predominance of nutritional deficiencies and infectious diseases toward degenerative and chronic diseases, such as diabetes and cardiovascular disease. Investigators have described at least five stages of transition. The first stage (pestilence and famine) includes nutritional deficiencies and infection and characterizes regions such as sub-Saharan Africa and rural South Asia. In the second stage (receding pandemics), during which the pandemics of infectious disease and malnutrition recede, diseases related to hypertension, such as hemorrhagic stroke, become more common. China is an example of a region in this stage. During the third stage (degenerative and man-made diseases), life expectancy improves, but high-fat diets, sedentary lifestyles, and cigarette smoking are introduced, allowing chronic, degenerative, and "man-made" diseases, including cardiovascular disease and ischemic stroke, to become more prominent. Urban India serves as an example of a country in this stage. As countries become more industrialized, populations are also

exposed to new environmental hazards. In a study conducted in Taipei, Taiwan, urban air pollution was associated with increased numbers of emergency admissions for cerebrovascular diseases. In the fourth stage (delayed degenerative disorders), there are increased efforts to prevent, diagnose, and treat these lifestyle-related diseases, which allow for a delay in their age of onset as well as the increase in degenerative diseases affecting the elderly. Western Europe and North America are considered to be in this fourth stage of the epidemiologic transition. Finally, a fifth stage may exist (social upheaval and social regression) in which social upheaval and war break down the existing health structures, leading to a resurgence of conditions seen in the first two stages as well as to the effects of violence and accidents. Post-Soviet Russia has been suggested as an example of this fifth stage.

As countries develop, they may also fall prey to the adverse consequences of a Western lifestyle (high-fat diet, sedentary lifestyle) before they fully emerge from the problems of underdevelopment. This phenomenon has been referred to as the *double burden* of disease and explains why countries in the middle levels of development have the highest rates of many illnesses. Developing and middle-income regions such as Latin America and urban India, for example, experienced increased incidence of cardiovascular disease while simultaneously facing the lingering effects of infection and malnutrition.

Neurologic disorders are also subject to this epidemiologic staging. At any given time, different regions throughout the world may be in different stages of this transition. In particular, empirical evidence of the epidemiologic transition of stroke was nicely described in the Sino-MONICA-Beijing project. In this community-based surveillance study, investigators examined temporal trends in stroke incidence in Beijing over two decades from 1984 to 2004, a particularly rapid period of economic development in China. Four characteristics of the epidemiologic transition were observed: declining incidence of hemorrhagic stroke due to improved treatment of hypertension, reduced case fatality due to improved treatment after stroke, increased age of stroke onset, and an expanded proportion of ischemic heart disease deaths with a decreased proportion of stroke deaths in the study population. Additionally, an increase in the incidence of ischemic stroke was found, which was felt to be secondary to increased atherosclerotic risk factors.

DISPARITIES

Populations can be stratified by geography and income, and there are often disparities in neurologic disorders based on these factors. The WHO recognizes 6 geographic regions (Africa, Americas, Southeast Asia, Europe, Eastern Mediterranean, and Western Pacific) and 14 subregions, stratified according to child and adult mortality in those regions. The World Bank categorizes countries into four groups on the basis of gross national income per capita: low, lower middle, upper middle, and high income. Varying types of neurologic disorders and degrees of disease burden occur in the different regions and income groups (**Figs. 1.3** and 1.4). In 2015, the lowest DALY rates from neurologic disorders were found in high-income areas and Latin America. The highest DALY rates were found in Afghanistan, Central African Republic, Guinea-Bissau, Kiribati, and Somalia. The prevalence of stroke was highest in Eastern Europe, central Asia, Oceania, Indonesia, Myanmar, and sub-Saharan Africa. The prevalence and DALY rates for Parkinson disease were highest in high-income regions and lowest in sub-Saharan Africa and Eastern Europe. This serves as an example of the disparities found among various countries when estimating disease burden. It is notable that countries in

the WHO high mortality stratum or low-income category face major challenges from diseases associated with poverty, underdevelopment, and ineffective health care systems.

Stroke

Worldwide, stroke accounts for approximately 10% of all deaths. The highest numbers of stroke deaths occur in Northern Asia, Eastern Europe, Central Africa, and the South Pacific. Systematic reviews of population-based studies from 28 countries showed that stroke incidence has increased in low-income and middle-income countries, whereas high-income countries have experienced a 42% decrease in incidence over the past four decades. According to the original global analysis contained in the estimates from the Global Burden of Diseases, Injuries, and Risk Factors Study, stroke mortality has decreased in the past two decades, whereas global stroke burden, rated in terms of yearly stroke survivorship, related deaths, and DALYs lost, has increased with the brunt of the burden in low-income and middle-income countries. Within high-income countries, improved health services and preventative stroke care may explain the reduction in stroke incidence, mortality, and DALYs lost and the converse for low-income and middle-income regions. In areas such as sub-Saharan Africa, there are high stroke mortality rates and low rates of reduction in DALYs lost.

Stroke disparities are not limited to the developing world; in fact, global disparities are reflected within nations. In the United States, racial minorities suffer increased stroke mortality and disability rates compared to non-Hispanic whites. African Americans have the highest mortality rates due to stroke and Hispanics have a higher stroke incidence than whites. Within the United States, a geographic distribution in stroke incidence and mortality can be discerned. In the southeastern United States, within a region referred to as the *Stroke Belt*, stroke mortality and incidence rates are increased. The highest rates are found along the coast, in Georgia and the Carolinas, in a region nicknamed the *Stroke Buckle*. Variations in the race or ethnicity of people comprising the population do not appear to explain the disparities in stroke mortality and incidence that exist in the southeastern United States because African Americans in that region seem to have increased stroke risks compared to African Americans in other parts of the country. The difference may be attributable to socioeconomic factors limiting access to care, producing an increase in the prevalence of stroke risk factors. It has been noted that, at the age that Medicare becomes available to elderly Americans, African Americans have no higher in-hospital mortality than do whites and no higher incidence in stroke rates or hypertension than do Hispanics. This provides indirect evidence that it is the lack of access to care that may be responsible for some of the racial and regional disparities.

Chronic Neurological Diseases

Global disparities in neurologic disease are not limited to stroke. In a population-based survey of residents older than age 65 years in seven countries with low and middle incomes (China, India, Cuba, Dominican Republic, Venezuela, Mexico, and Peru), dementia was overwhelmingly found to be the most important independent contributor to disability for elderly people in these countries. Chronic disease disability in countries with low and middle incomes is expected to increase by 224% in the least developed regions over the next four decades. Similarly, in a cross-sectional study of elderly Chinese people living in Hong Kong, dementia, stroke, and Parkinson disease were the chronic conditions most strongly associated with severe debility.

Access to Care

Limitations in neurologic resources and variability in resource allocation to neurologic problems contribute to the disparities in the global burden of neurologic disease. In the second edition of the WHO Project Atlas launched in 2017, there were marked disparities in availability of adult neurologists, child neurologists, and neurosurgeons across regions and income strata. The European region reported the largest neurologic workforce, with a median of 9 per 100,000 population, whereas the African region reported a median of 0.1 per 100,000 (Fig. 1.5). The World Bank income groups also demonstrated similar differences, with high-income countries reporting a median of 7.1 per 100,000 people, compared with low-income countries reporting a median of 0.1 per 100,000 (Fig. 1.6). This Neurology Atlas illustrates the existence of inadequate resources for neurologic disorders in most countries and highlights the inequalities in access to neurologic care particularly present in low-income countries. This provides an example of the need for an increase in neurology services and training in lower income countries to allow for adequate care to be provided and limit the inequities.

FIGURE 1.5 Median neurologic workforce per 100,000 population, by World Health Organization region. Abbreviations: AFR, African Region; AMR, American Region; EMR, Eastern Mediterranean Region; EUR, European Region; SEAR, Southeast Asian Region; WPR, Western Pacific Region. (From World Health Organization. *Atlas: Country Resources for Neurological Disorders*. 2nd ed. Geneva, Switzerland: World Health Organization; 2017: Figure 11. License: CC BY-NC-SA. 3.0 IGO.)

Variation in allocation of attention and research resources may contribute to the disparities seen in neurologic care worldwide. For example, of the 685 manuscripts published in the *Annals of Neurology* from 2005 through 2008, 91% had a corresponding author in either North America or Europe. Thus, 97% of manuscripts were produced in high-income countries where only 15% of the global population resides. Furthermore, the vast majority of clinical studies of neurologic disease describe people in high-income countries. A paradox has been observed within the pharmaceutical research realm, whereby 90% of medical research funds are spent on 10% of the world's population. Apparently, research and development expenditures for diseases of poverty, including malaria, tropical diseases, and tuberculosis, are considered more likely to provide low returns and thus are considered high risk for failure and are not pursued.

SOCIOCULTURAL DIFFERENCES IN INTERPRETATION OF DISEASE

Cultural differences in disease screening, reporting, and management may contribute to the variation in identified global neurologic disease burden. A skew in the number of neurologic diagnoses identified in developing countries, as compared to high-income countries, might be a result of neurologically afflicted patients in developing countries not coming to medical attention. In one analysis of health systems constraints in Timor-Leste, one of the poorest countries in Asia, it was found that poverty, strong beliefs in traditional medicine and healers, and low levels of education were barriers to people seeking care. Diagnostic equipment that is crucial for neurologic care, such as electroencephalography, electromyography, computed tomography, and magnetic resonance imaging, was absent. There were no manufacturers of medicine in the country, requiring importation of all necessary medicines.

In a study examining the reportable neurologic diseases in refugee camps in 19 countries within Africa, the Eastern Mediterranean, and Southeast Asia, a variety of diagnoses were revealed. Epilepsy represented more than 9 out of every 10 visits for neurologic disease in these refugee camps. The underlying causes of epilepsy in refugee camps, although unknown, were presumably similar to those for other inhabitants in the region, including perinatal injury, head trauma, cerebral malaria, and previous stroke. Within refugee camps throughout sub-Saharan Africa, the monitoring of meningitis and newer initiatives for vaccination were found to be crucial for preventing epidemic outbreaks, particularly those due to *Neisseria meningitidis*. However, there were limitations in accurate reporting in these regions, with many of the diagnoses not being verified by physicians and conditions such as meningitis being unlikely to have received cerebrospinal fluid confirmation. Regional and cultural differences in diagnosis and disease reporting can have an impact on the accurate assessment of the total global burden of neurologic disease.

Regional differences in the management of neurologic disease are also seen worldwide. Infectious disease, including meningitis, encephalitis, and cerebral malaria, is a major cause of critical neurologic illness in developing countries. Ischemic and hemorrhagic stroke, severe head injury, and epilepsy are major unaddressed causes of morbidity and mortality in many developing countries. In addition, neurologic manifestations of rabies, tetanus, eclampsia, and tuberculosis contribute to the burden of disease in these regions. The largest share of tuberculosis infection is seen in Africa and Asia where resource constraints hamper efforts to control new infections and prevent drug resistance. Infections of the nervous system by *Mycobacterium tuberculosis*, including meningitis, tuberculoma, tuberculous abscess, and nonosseous spinal tuberculoma, affect more than 10% of patients in the region. Tuberculosis is the leading cause of death in HIV-infected individuals in this population. Many low- and middle-income countries with high tuberculosis burdens have limited laboratory capacity to perform smear microscopy or run cultures for drug susceptibility testing. Unfortunately, in low-resource settings, patients often present late for medical care and are sometimes misdiagnosed and treated inappropriately, which can lead to a more severe clinical course. In some of even the least developed countries, governments fund hospitals that include intensive care unit–level care and, in addition, humanitarian efforts and military hospitals also contribute to offer some form of neurologic disease management, showing that neurocritical care can sometimes be practiced even in extremely resource-poor locations. There are, however, limitations in available resources. Many medications are not universally available. For example, although tissue plasminogen activator is a standard of care in high-income settings, developing countries still struggle with poor availability of this drug. Alternatives such as snake venom or urokinase may be employed instead despite an absence of evidence of their efficacy or optimal dose. Finally, there remains a need for attention to neurologic recovery after the illness to allow for a seamless continuum between prevention, intervention, and rehabilitation from neurologic illness.

Cultural differences worldwide are an additional contributor to the differences seen in neurologic care around the world. For example, in many countries, patients with recurrent seizure may be considered to be possessed rather than as having epilepsy. In a cross-sectional study performed in Dar es Salaam, Tanzania, it was shown that of 100 traditional healers interviewed, 30% believed that epilepsy was caused by witchcraft, whereas 19% thought epilepsy had a genetic origin that could be inherited. The traditional healers treated epilepsy with up to 60 different plants, some of which have demonstrated anticonvulsant activity. Among the Maasai population living throughout East Africa, who hold fast to their traditional and nomadic lifestyle, patients presenting with HIV/AIDS, epilepsy, and cerebral palsy are treated in remote sites using "bush medicine" within tents and working by sunlight with no electricity. In Maasai traditional medicine, herbs, roots, and bark are commonly boiled down into a soup. These examples serve as reminders that cultural differences in disease management and medication usage may vary greatly throughout the world.

There are a number of international organizations dedicated to neurologic care globally. Several member organizations within the United Nations, including the WHO, the World Bank, and the United Nations Children's Fund, have played roles in policy matters related to neurologic disease. Nongovernmental organizations provide care for people with neurologic disease in some of the least developed regions globally. Similarly, the World Federation of Neurology is an international organization of country-level neurologic societies composed of community-based and academic neurologists, who have successfully come together in the past to tackle international issues within neurologic disease.

SUMMARY

Neurologic disease has a tremendous impact on human illness and mortality globally. Despite the challenges in quantifying the burden of neurologic disease and assessing its impact on populations throughout the world, several points are clear. Neurologic diseases, whether they are primary or secondary, more frequently cause disability than death. This has been an obstacle to research employing common measures of disease impact. Additionally, disparities in incidence, diagnosis, disease management, and outcomes for patients in different geographic and socioeconomic sectors proffer a unique signature on the global burden of neurologic disease.

Global Delivery of Neurologic Care 2

Hiral Shah, Serena Spudich, and Kiran T. Thakur

KEY POINTS

1. Over 50% of the world's population cannot obtain essential health services, including basic neurologic care, and this will only continue to increase in the coming years unless significant measures are taken.
2. High-quality neurologic care is safe, accessible, affordable, effective, equitable, and with a focus on human rights.
3. Coupled with the overall limitations in access to care and treatment for many neurologic disorders in resource-limited settings, stigma often adds to the burden of disease among vulnerable populations in these regions.

GAPS IN GLOBAL ACCESS TO NEUROLOGIC CARE

Over one billion people are living with neurologic conditions globally, with more than 50 million individuals living with epilepsy and approximately 47 million with dementia. Neurologic disorders are now the leading cause of disability-adjusted life years (a measure of one lost year of healthy life) worldwide and the second leading cause of death (refer to chapter on Global Burden of Disease, Elkind et al). The global burden of neurologic disorders has increased exponentially over the past two decades, with a significant rise in noncommunicable conditions, including cerebrovascular disease, epilepsy, and dementia. The growing number of people living with neurologic disorders, particularly an aging global population, necessitates plans to enhance knowledge among health care providers in the diagnosis and management of neurologic conditions. Despite the need, current neurologic resources and services are disproportionately scarce in resource-limited settings, where much of the burden of disease exists. Major disparities exist by World Health Organization (WHO) region and World Bank income categories with regard to the neurologic workforce (Fig. 2.1). Data show a significant deficit in adult and pediatric neurologists as well as neurosurgeons. Over 50% of the world's population cannot obtain essential health services, including basic neurologic care, and this will only continue to increase in the coming years unless significant measures are taken.

Providers in many low-income countries face additional challenges given lack of resources to provide adequate care, with the poorest sectors most affected by these constraints. Clinicians, researchers, and policy makers alike should be aware of these trends and limitations to appropriately plan for services to provide comprehensive neurologic care in the future.

This chapter introduces concepts related to existing challenges and barriers to delivery of care for neurologic conditions worldwide, with a focus on the unique challenges in resource-limited settings. We present strategies and approaches for overcoming these barriers and effectively building infrastructure and capacity for care of the neurologic patient in a variety of settings. Throughout the chapter, specific examples are provided of challenges or strategies relevant to global delivery of care (see Boxes 2.1 to 2.4).

Components Required for Delivery of Neurologic Care

Optimal care delivery designed to improve the neurologic health of individuals, families, and communities should consider the local context in order to best organize resources and the health care workforce. High-quality neurologic care is safe, accessible, affordable, effective, equitable, and with a focus on human rights. Service delivery requires integration and coordination among various levels of care (primary, secondary, and tertiary) as well as among disciplines (pain, palliative care, mental health, rehabilitation, social services), where available. Information sharing via technologic advances can enhance the care process and improve quality and safety. To ensure adequate and comprehensive neurologic care, several components need to be in

FIGURE 2.1 Median neurologic workforce per 100,000 population, by World Bank income group. (From World Health Organization. *Atlas: Country Resources for Neurological Disorders*. 2nd ed. Geneva, Switzerland: World Health Organization; 2017.)

place. Governments must support efforts for adequate health and social care services. One mechanism is universal coverage provided by governments, although often a mix of public and private funding of health services is common in low-, middle-, and high-income settings. Optimally, governmental policies and legislation should be implemented to protect vulnerable populations with neurologic disorders, such as legislation to address stigma and civil rights barriers. Leadership to champion the cause of improving health care and social supports for people living with neurologic disease, in both the public and private sectors and intersectoral collaboration of these advocates, is necessary to address the challenges the population faces.

Training of specialists in neurologic care is also essential. Country level resources often determine the level and type of training that is available and required. At the primary care level, basic training is needed in the diagnosis and management of neurologic diseases for physicians, nurses and other allied health professionals. Existing resources provided by WHO such as the WHO Mental Health Gap Action Program intervention guide and associated training materials can be adapted and implemented in the local context. At the secondary level, systems of referrals, task-shifting to train nonmedical providers in the provision of neurologic care is important. At times, this includes collaboration with local traditional healers. At the tertiary level, additional specialist training is needed, although challenges exist to addressing adequate training and retention of specialists.

Additionally, availability of adequate resources, including the health care work force, diagnostics, and medicines is critical to providing comprehensive neurologic care and is often particularly restricted where resources are limited (see in the following text). Health care costs associated with neurologic disorders place a strain on funding sources (both public and private), highlighting the importance of an appropriate financing and insurance plan.

CHALLENGES IN ADDRESSING NEUROLOGIC DISORDERS

Stigma Related to Neurologic Disorders

Stigma has been defined as "the situation of the individual who is disqualified from full social acceptance" and occurs at the individual, interpersonal, and societal level with varying consequences. Coupled with the overall limitations in access to care and treatment for many neurologic disorders in resource-limited settings, stigma often adds to the burden of disease among vulnerable populations in these regions. Stigma, however, is not a phenomenon isolated to developing regions of the world but is universally felt and experienced, particularly among people with neurologic diseases. For instance, individual stigma, or internalized stigma, refers to the individual's experience of discrimination or awareness of negative attitudes toward one's condition. This becomes an internalized stereotype that has negative consequences for the individual, including one's physical health as it affects health care-seeking habits and has significant psychiatric comorbidities, including depression and anxiety, which are correlated with poor self-esteem and social exclusion. Interpersonal stigma refers to the negative actions of others toward the individual with the condition. And, societal stigma refers to the resultant laws or policies of society that are taken toward the individual. Studies have shown that people with epilepsy who are stigmatized have a lower quality of life (as a consequence of individual and interpersonal stigma) and unequal access to health and life insurance, limited access to school and fewer employment opportunities (consequences of societal stigma). Stigma further limits disclosure of health conditions, serving as a barrier to measuring the full global burden of neurologic diseases. Stigma is often rooted in misperceptions and knowledge gaps of a disease entity. For an example, see Box 2.1.

BOX 2.1 High School Students' Knowledge and Attitudes of Epilepsy in Southern India[a]

A study was conducted to determine awareness, attitudes, and beliefs that people hold on epilepsy. The participants consisted of high school 10th graders (Kerala, Thrissur, Malappuram, and Palakkad, India). The study was performed by surveying participants with 24 yes-or-no questions and carried out by medical social workers. Although 98% of respondents had previously heard or read about epilepsy, nearly 60% classified epilepsy as a mental illness, whereas 50% believed it was a brain disorder. Additional misbeliefs were observed among the group of participants, such as believing epilepsy is a contagious condition (13.9%). Regarding attitudes about the condition, the majority believed that epilepsy posed a barrier to living a happy life (62.4%) and ability to have a normal sexual life (43.2%). In relation to measures to be taken in the event of a seizure, visiting the hospital was a common response (62.3%), yet about 24% suggested sprinkling water on the face of victims, and 60% believed in the efficacy of Ayurvedic treatment.

[a]Thapa L, Bhandari TR, Shrestha S, Poudel RS. Knowledge, beliefs, and practices on epilepsy among high school students of Central Nepal. *Epilepsy Res Treat*. 2017;2017:6705807. doi:10.1155/2017/6705807

Challenges in Health-Seeking Behavior

Studies have identified several social factors associated with poor health-seeking behavior in neurologic conditions. Some of these factors include residing in rural areas, having a lower level of education and poor literacy, and poor socioeconomic status. Other factors including physical access to services and perceived quality of service play an important role. Overall, lower health-seeking behavior is linked to worse health outcomes and increased morbidity and mortality and is a significant barrier to adequate care and treatment for neurologic conditions worldwide. See Box 2.2 for an example of factors associated

BOX 2.2 Barriers to Care for Patients With Nodding Syndrome in Northern Uganda[a]

Nodding syndrome, a cause of epileptic encephalopathy afflicting children predominantly in South Sudan, Uganda, and Tanzania, is a disorder characterized by episodic head nodding, which progresses to multiple seizures types and cognitive decline. A study performed in Northern Uganda characterized help-seeking and treatment practices for nodding syndrome among various stakeholders, including health care professionals, district leaders, and caregivers of children with nodding syndrome. Identified challenges included the following:

- Health system factors, for example, long distances to facilities, frequent unavailability of medicines, few health care providers, and long waiting times
- Contextual and societal challenges, for example, lack of money for transport and medical bills

[a]Mwaka AD, Okello ES, Abbo C, et al. Is the glass half full or half empty? A qualitative exploration on treatment practices and perceived barriers to biomedical care for patients with nodding syndrome in post-conflict northern Uganda. *BMC Res Notes*. 2015;8:386. doi:10.1186/s13104-015-1323-5

with health-seeking behavior in nodding syndrome, an epileptic encephalopathy described in Sub-Saharan Africa.

Limited Global Access to Diagnostics and Therapeutics for Neurologic Disorders

Significant disparities in the availability of diagnostics for neurologic conditions exist, both regionally and by World Bank income categories. Of the recently published WHO essential diagnostics list, only 3 of the 113 diagnostic tests pertain to neurologic disorders, which are the cerebrospinal fluid (CSF) cryptococcal antigen test for diagnosis of cryptococcal meningitis, the CSF nucleic acid amplification test for diagnosis of central nervous system tuberculosis, and CSF bacterial culture. Lack of adequate diagnostic tests (ie, serum and CSF testing, electromyography/nerve conduction study, electroencephalogram, computed tomography of the brain) may lead to less efficient use of already-scarce resources in many settings, such as medications and health care personnel. A lack of diagnostics also limits the ability to assess the epidemiology of neurologic disorders. Closing the neurodiagnostic gap requires investment in several domains, including building diagnostic infrastructure, hiring and training of staff to use and maintain equipment, training in the interpretation of diagnostic studies, increasing access to limited technologic resources via new methods such as mobile clinics, and access and integration to more cost-effective tests. There is a critical need to strategize on how to efficiently and affordably integrate diagnostics into current health care systems globally.

The availability and accessibility of treatments for neurologic disorders also shows significant disparities. Literature on the epilepsy treatment gap shows that over three-quarters of people living in resource-limited settings do not have routine access to antiepileptic medications. Lack of effective screening and approval mechanisms for new drugs as well as cost-effective purchasing mechanisms and distribution systems limits the availability of standard medications for neurologic disorders. Availability of medications may be increased through aid programs and improvements in regional purchasing and distribution systems.

Gaps in National Policies and Guidelines for Brain Health

Government and nongovernmental policies and guidelines for neurologic disorders help to delineate standards and protocols to optimize neurologic care (Box 2.3). In the latest WHO-World Federation of Neurology–led survey, 24% of countries report neurologic health policies, 41% of countries report national or subnational legislation on epilepsy, and 30% report legislation relating to people with dementia. The lack of guidelines and policies for neurologic care undermines adequate neurologic care, as these mandate adequate supply of essential diagnostic tests and medicines, standardizing training and workforce requirements, standardizing procedures for the care of brain disorders in a tiered health care system, and defining operational requirements.

Approaches and Strategies to Improve Delivery of Neurologic Care Globally

Lower income countries (LIC) and lower-middle income countries (LMIC) face the highest burden of neurologic diseases with significant resource limitations requiring novel approaches for care delivery. There are several ongoing efforts to improve neurologic care delivery globally, in both LIC and LMIC countries as well as resource-limited settings (eg, rural locations) in high-income countries. Interventions to improve care delivery can target many aspects of the continuum of care ranging from advocacy efforts, policy initiatives, health care systems strengthening, training, and capacity building to service delivery.

Collaborative Partnerships and Coordinated Action

Collaborative effort across industry, government, and nongovernmental sectors is a mechanism important to the prioritization of neurologic disorders. This effort can lead to increased investment; implementation of policies, plans, and legislation; and engagement of multisectoral stakeholders in government

BOX 2.3 World Stroke Organization Global Stroke Services Guidelines and Action Plan[a]

The Global Stroke Services Action Plan is a tool to identify essential elements in stroke care across health models with varying complexity and access to stroke services. Checklists for stroke service planning are tiered by level: minimal, essential, and advanced. This global guideline recognizes the variability of local resources when assessing requirements and developing guidelines to optimize stroke care.

Advanced stroke services	Essential stroke services	Minimal healthcare services
❑ Access to advanced diagnostic services ❑ Access to physicians with stroke expertise ❑ Access to advanced interventions in addition to tPA, such as interventional radiology and neurosurgery ❑ Access to specialist rehabilitation therapists ❑ Access to community programs for recovery after stroke ❑ Fully coordinated stroke care provided across geographically discrete regions	❑ Access to basic diagnostic services—laboratory, ECG, CT scan, ultrasound ❑ Access to nurses ❑ Access to physicians, although may not be stroke specialists ❑ Access to acute thrombolysis with tPA ❑ Access to elements of stroke unit care, including members of an interdisciplinary stroke team ❑ Access to rehabilitation services ❑ Access to stroke prevention therapies such as aspirin, lifestyle change recommendations, blood pressure management ❑ Limited coordinated stroke care provided across geographically discrete regions	❑ Variable access to healthcare workers (nurses or lay workers) ❑ Very limited access to physicians ❑ No access to diagnostic services or hospital care ❑ Limited access to the most basic lifestyle preventative advice ❑ Care provided in local communities without coordination across defined geographic regions

Abbreviations: CT, computed tomography; ECG, electrocardiogram; tPA, tissue plasminogen activator.

[a]Lindsay P, Furie KL, Davis SM, Donnan GA, Norrving B. World Stroke Organization global stroke services guidelines and action plan. *Int J Stroke*. 2014;9 (suppl A100):4-13.

and scientific agencies, professional, and advocacy organizations. At the policy level, interventions can address financing, leadership, and governance. Approaches of transitioning from vertical, disease-focused programs to horizontal, systems-focused perspectives can be employed at the primary health care level. Additional efforts can target health financing strengthening. Collaborative partnerships have led to health policy-level advocacy, improved measurement, and awareness-raising campaigns.

For example, a coordinated global response has been imperative to begin to address the challenge of dementia. In 2012, WHO published *Dementia: A Public Health Priority*, which provided an overview of the impact of dementia worldwide, with a focus on LIC and LMIC regions, where impact is high with low preparedness. This report gained support among world leaders, researchers, and stakeholders, spurring the G8 Dementia Summit that launched the Global Action Against Dementia. They agreed to 12 specific commitments and the development of a coordinated international research action plan. The Global Dementia Action Plan on the Public Health Response to Dementia 2017-2025 was launched and includes clear goals and targets for consideration by the 17th world health assembly. This work was synergistic as the WHO launched The Global Dementia Observatory, a data and knowledge exchange platform to provide a mechanism for continuous monitoring of the dementia landscape and dissemination of information. The observatory focuses on data domains of policies, service delivery along with information and research. Together, they built the Global Dementia Observatory monitoring framework (Fig. 2.2).

Another example is the Global Campaign Against Epilepsy, formed through partnerships with the WHO, International League Against Epilepsy, and the International Bureau of Epilepsy. Because of the Global Campaign Against Epilepsy, numerous community-based projects have been implemented. For further information, please see Box 2.4.

BOX 2.4 The China National Epilepsy Project[a]

In China, a large community-based project was implemented in five provinces to reduce the epilepsy treatment gap by training and educating health care providers, raising public awareness to reduce stigma, identifying prevention approaches, and integrating epilepsy care into the local health systems. Primary health care physicians were trained to diagnose and treat epilepsy. More than 2,400 people with epilepsy were treated, with 25% achieving seizure freedom and 70% with improved outcomes. The treatment gap was estimated to be reduced by half. Care-seeking behaviors increased through the implementation of awareness raising efforts with community education that epilepsy is a treatable condition. Given the positive results, the initial project was scaled up, with the establishment of The China National Epilepsy Project. The National Project has serviced 240 counties across 19 provinces where 120 million people reside in rural areas. This expansion led to treatment with antiseizure medicines of more than 110,000 people with epilepsy. The China National Epilepsy Project is exemplary of effective rural and primary health care of epilepsy.

Improving Access to Neurologic Care: Primary Care Workforce

One mechanism to combat the shortage of specialists is to strengthen the primary care system's capacity to provide care for people with neurologic conditions. Primary care represents the gateway to medical care for many people worldwide and is thus a logical setting to first address care for people with neurologic disorders. Effective primary prevention for neurologic conditions

FIGURE 2.2 Global Dementia Observatory. (From World Health Organization. Some rights reserved. This work is available under the Creative Commons Attribution-NonCommercial-ShareAlike 3.0 IGO licence [CC BY-NC-SA 3.0 IGO; https://creativecommons.org/licenses/by-nc-sa/3.0/igo].)

is an essential step in curbing the burden of neurologic disorders. Neurologic care by primary health care providers is reported to be available in 91% of countries where no neurologic expertise exists, according to the WHO–World Federation of Neurology atlas, although the level of training and expertise in diagnosing and managing neurologic conditions is unknown. Utilizing the primary care workforce has been identified as one of the most feasible and cost-effective models to build neurologic care support, particularly in resource poor settings. This must be tempered with the realities of primary care practice in many regions, including a lack of training in neurology, overwhelming patient volumes, and a myriad of other challenges, which often leave primary care practitioners without the tools and resources necessary to diagnose and manage neurology patients. Careful planning to incorporate neurologic care in an already overburdened system is thus required. Complex neurologic conditions, for example, may be recognized early to avoid complications in a primary care setting and referred for early intervention to a higher level of care.

TELEMEDICINE AND INFORMATION AND COMMUNICATION TECHNOLOGY

Synchronous Approaches

Given high rates of Internet penetration and availability of mobile phones in developing countries, telemedicine and use of information and communication technology may be a viable option to allow those with neurologic conditions to gain access to the appropriate providers and specialists and overcome geographic and financial barriers to seeking care. Telemedicine and information and communication technology is an attractive and interactive method to provide diagnosis and treatment by medical providers as well as ancillary services including speech-language therapists and mental health services. Telemedicine has many advantages, reducing travel and wait times, reducing cost for health systems (eliminating some time and space constraints, reducing human resources needed to provide care), as well as improving efficiency of the providers. There remain challenges in terms of technology concerns (lack of equipment, connectivity), licensure and insurance payment mechanisms, as well as concerns about privacy and security.

Asynchronous Approaches

Telemedicine also include asynchronous approaches such as video recordings to capture function, delivery of information and skills training, as well as support systems such as online health communities. Online health communities can be a resource for knowledge exchange and improve self-management skills. Such asynchronous approaches have the advantages of being flexible, providing support at any time (even at night), person-based, client friendly, and focused on self-management and self-efficacy.

Training Approaches to Build Capacity

Another mechanism to build a cadre of neurology specialists globally is the development of training programs and centers, which are tailored to local needs and resources. Often, these programs are based at tertiary care hospitals, which serve as a referral center for complex neurologic and neurosurgical patients, allowing for concentration of expertise, diagnostics, and therapeutics. Neurologic centers of excellence can also provide leadership to establish priorities and develop regional and national planning strategies, guidelines, and policies for neurologic disorders. These programs require that trainees are retained to build further capacity to recognize and treat neurologic conditions.

Community Engagement

Perceptions of neurologic conditions such as epilepsy, cerebral palsy, and cerebrovascular disease are influenced by social and cultural factors and thus providing care that is culturally congruent is crucial. Cultural perceptions underlying neurologic conditions often serve as barriers to care, although medical personnel who work alongside communities to break down these barriers have shown increased success in reducing stigma. Engaging community members as active participants of service delivery is critical to successfully combat misperceptions. By sharing of information and engaging in active dialogue, ambiguities and stigma around prevention and treatment of neurologic conditions may be reduced.

Programs Aimed to Raise Public Awareness

One of the central goals of public awareness campaigns is to tackle stigma and discrimination. Other major goals include improving prevention strategies, enhancing access and adherence to treatment, and promoting research. Public awareness campaigns have had success when targeted and tailored with clear outcomes based on the needs of those affected with neurologic conditions. Many factors must be considered in deciding on an appropriate campaign strategy, including the ethnographic makeup of the target audience. Campaigns increasingly pull together a variety of stakeholders—including national and international health and advocacy organizations, policymakers, and patient groups—to undertake these costly and complex endeavors.

CONCLUSION

The expected increase in the number of individuals with neurologic conditions, particularly in resource-limited settings, necessitates careful, urgent planning by governments and other stakeholders to ensure adequate and accessible care. With a significant global shortage of the neurologic workforce, improving neurologic care will require innovative strategies within existing health systems. Focusing on effective primary prevention strategies and utilization of the primary care workforce will be essential, especially given the growth in the number of individuals worldwide with noncommunicable neurologic disorders. Epidemiologic and health-services research will provide evidence needed to set goals and priorities for neurologic conditions, particularly in resource-limited regions. Additional novel strategies such as telemedicine and information technology can be used for training, assessment, and care delivery.

Neurologic History Taking, Localization, and Differential Diagnosis 3

James M. Noble

KEY POINTS

1. A high yield neurologic history requires a structured approach, framed around a solid basis of knowledge of disease localization and etiologies.
2. Organization of the neurological history is framed around common diagnoses and can't miss diagnoses, considered with frequently encountered neurologic problems.
3. Universal elements of the history, including past medical history, review of systems, and social and family histories are specifically framed to an appropriate neurologic context.
4. Diagnostic reasoning follows the synthesis of a well-rounded history and the neurologic examination and may lead to rereview of the history to clarify unexpected findings.

INTRODUCTION TO CLINICAL DIAGNOSTIC REASONING

Making a neurologic diagnosis requires a systematic approach to the patient, built on a foundational awareness of neuroanatomy and a broad range of neurologic diseases, and paths toward establishing a diagnosis in each. The history and physical examination provide essential, complementary, and readily accessible data. Together, they comprise the most meaningful information of the initial (and often subsequent) steps of clinical diagnostic reasoning, informing the diagnostic workup, and treatment plans. This chapter discusses the approach to developing a patient-specific neurologic history and should be reviewed in context with the neurologic examination (specifically covered in Chapter 4 and further in Section III: Common Problems in Neurology) and selective use of diagnostic testing (Section IV: Diagnostic Tests).

INTENTIONAL EXPLORATION OF THE PATIENT HISTORY

Fundamental to assessment of any patient presenting with a neurologic problem is development of the history specifically tailored to the patient. In neurology, this task can at first seem challenging and relates to the complexities of nervous system and a broad array of presentations of different kinds of neurologic disorders, as well as potentially subtle differences within each group of disorders. It is therefore necessary to know which diagnostic possibilities are reasonable considerations for a particular patient, best accomplished by starting with a broad approach. A strong determinant of ultimately missing a diagnosis is not considering it early on in the diagnostic search. Furthermore, overreliance on laboratory tests and technology can lead to a scattershot approach that is uninformed by clinical reasoning and appropriate differential diagnosis and most importantly prone to errors and delaying appropriate therapy.

The clinical data obtained by a careful history and physical examination are used to address four questions:

- **What anatomic structures of the nervous system are affected?** It is usually not possible to make a specific etiologic diagnosis without knowing what parts of the nervous system are affected. In addition, knowing the probable anatomic substrate restricts the etiologic possibilities. Thus, making an accurate *anatomic diagnosis* should be the first step in analyzing a neurologic disorder. Clues to identifying the anatomic sites of neurologic disorders are discussed in the following section and later in this chapter.
- **What is the nature of the neurologic disorder?** An individual patient's symptoms usually cluster into broad syndromes or categories of disease: developmental disorder, peripheral neuropathy, acute encephalopathy, progressive dementia, parkinsonian syndrome, cerebrovascular syndrome, and so on. A syndromic diagnosis assists in clarifying the nature of the disease and further focuses on possible specific causes.
- **What are the most likely etiologies for the patient's illness?** These derive from consideration of the anatomic and syndromic diagnoses in light of the tempo (rapid or slow) and course (fixed from onset, steadily progressive, or stepwise) of the illness, relevant past history and family history, and whether there is evidence of systemic involvement. The possible etiologies listed in order of probability constitute the differential diagnosis, and this in turn determines which laboratory tests need to be ordered and the urgency with which the evaluation should proceed.
- **What diagnostic possibility cannot be missed?** As much as it is important to focus on the most likely diagnosis, it is also important to effectively assess and hopefully exclude a "can't miss" diagnosis, which could lead to morbidity or mortality. Of course, sometimes, the most likely diagnosis is the most serious "can't miss" diagnosis.

An experienced clinician will likely deal with these four questions simultaneously and differing orders, patient to patient. To take an obvious example, if a patient suddenly becomes speechless

or awakens with a hemiplegia, the diagnosis of stroke is made. The location and etiology of a large and potentially fatal stroke in the territory of the dominant hemisphere's middle cerebral artery is then deduced from findings made on examination, further confirmed by neuroimaging. If there are no surprises in the imaging study (eg, demonstration of a tumor or vascular malformation), further laboratory tests might be considered to determine the precise cause of an ischemic infarct.

Identifying Localization

Aspects of the patient's history may suggest the nature of the disorder; specific symptoms, corroborated by signs on examination can suggest the site of the disorder. These are shown further in Table 3.1.

TABLE 3.1 Approach to Diagnosis Based on Localizing Features in the History

Probable Localization	Key Features in the History
Cerebral	• Seizures or focal symptoms that may be attributed to a particular area of the brain: hemiplegia, aphasia, or hemianopia are examples. • Generalized manifestations of cerebral disease are seizures, delirium, and dementia.
Brainstem disease	• Cranial nerve palsies, cerebellar signs of ataxia of gait or limbs, tremor, or dysarthria. • Crossed features (eg, contralateral face vs arm and leg weakness) • Dysarthria may be the result from incoordination in disorders of the cerebellum itself or its brainstem connections. • Cranial nerve palsies or the neuromuscular disorder of myasthenia gravis may also impair speech. • Ocular signs have special localizing value.
Basal ganglia	• Involuntary movements including tremor
Spinal cord	• Spastic gait disorder and bilateral corticospinal signs, with or without bladder symptoms • If there is neck or back pain, a compressive lesion should be suspected. • If there is no pain, demyelinating disease is likely. • The level of a spinal compressive lesion is more likely to be indicated by cutaneous sensory loss than by motor signs. • The lesion that causes spastic paraparesis may be anywhere above the lumbar segments.
Peripheral nerve disease	• Usually causes both motor and sensory symptoms (eg, weakness and loss of sensation). The weakness is likely to be more severe distally, and the sensory loss may affect only position or vibration sense. • More specific localization follows segmental or dermatomal loss of sensation.
Neuromuscular junction disorders and myopathic diseases	• Limb or cranial muscle weakness without sensory symptoms • Cramping suggests myopathic disorders but can also be reported in motor neuron and basal ganglia diseases. • Fatigability and/or facilitation of strength with repeated activity suggests a neuromuscular junction disorder.

HISTORY OF PRESENT NEUROLOGIC ILLNESS

Sources of Information

A reliable and accurate history is essential and should be obtained directly from the patient whenever possible. However, in neurologic disorders, it is often necessary to verify the patient's account or obtain additional information by speaking with relatives or close friends. Corroborating and developing the history through collateral sources is particularly important if the illness has compromised the patient's cognitive abilities, especially if memory or language is impacted.

Electronic health systems have enabled rapid discovery and communication of past history, but they have also become prone to plagiarism and riddled with diagnostic inaccuracies carried forward or diagnostic momentum carried in the wrong direction. Whenever possible, obtain information from primary sources and verify them through direct, first-hand means.

Approach to Taking the History

The manner in which questions are asked can have a strong impact on findings and impressions developed from the neurologic history LEVEL 3.[1] Whenever possible, begin with asking open-ended questions and transition to targeted questions based on the differential being formulated around the presenting problem ("chief complaint"). To avoid errors, it is important that the physician avoids leading questions and clarifies what the patient means by ambiguous terms, such as *dizziness* or *weakness*. These more focused questions are intended to refine the likelihood of disorders in the differential diagnosis. Along with confirming questions, questions should be asked to refute unlikely considerations or to explore for potentially similar syndromes or competing causes. For example, in a patient being evaluated for seizure, a series of questions exploring for potential cardiogenic cause of syncope would be necessary, given overlapping features including sudden loss of consciousness as well as observed ictal behavior. Discrepancies and inconsistencies in details obtained by different examiners are often the source of diagnostic confusion and must be resolved.

The initial approach to developing the history is principally informed and shaped by a well-rounded neurologic knowledge and broad-based experience inherent to the interviewing physician. Knowledge gaps are thought to be the primary pitfall in diagnostic reasoning errors. Experience and knowledge can enable generation of *illness scripts*, which are vignettes of prototypical cases of disease against which a clinician can judge the relative fit of the patient being interviewed. Similarly, some experienced clinicians may be able to draw on error scripts, identifying prior pitfalls in diagnostic thinking in order to refine the diagnosis. Depending on the context, inherent cognitive biases, or "cognitive dispositions to error," may further influence how clinicians synthesize a diagnosis.

Primary Components of the History

Localization

In evaluating most patients with neurologic symptoms, determining localization is the most essential component of the neurologic history. To a patient, *location* can describe where in the

body the problem is perceived or observed, in contrast to *localization*, which refers to where the problem can be placed as precisely as possible in the neuraxis. It is worthwhile spending time refining the exact location of symptoms and potential localization of the problem. Although many neurologic presentations, such as stroke will have a singular localization, ranging from small to large territory brain involvement with infarction, other neurologic disorders may have a multifocal, systemic, or diffuse presentation. Multifocal presentations must be considered in severe trauma (exploring for spinal injury concomitant to brain injury) or neurologic presentations of metastatic cancer.

Knowing the *handedness* of neurologic patients is essential in localizing many cerebral disorders, given known associations with language dominance, particularly with right handers (upward of 93% left hemispheric language dominance in right handers but closer to half left hemispheric dominance in left handers who also have overrepresentation of language codominance). Although less common in recent times, some left-handed persons may have been forced to become right handers in early life to align with cultural norms. Ambidextrous persons make clinical prediction of language dominance difficult.

Neurologic presentations with a diffuse localization but with a singular problem include neuromuscular junction disorders and myopathy. Furthermore, some neurologic disorders will suggest diffuse but not necessarily focal neurologic localization, such neurodegenerative cognitive disorders, which often present with bilateral multilobar cortical features as well as parkinsonism suggesting additional localization in the basal ganglia and other subcortical structures.

Timing, Onset, Tempo, and Duration

There are several key features of any medical neurologic or neurologic problem. The first is identifying the *timing* or important timepoints related to the presentation. Timing refers to the pace of events leading to presentation, ideally trying to find a causative or precipitating factor, or the sequence of several related symptoms, which evolve one after another or in parallel. Understanding timing is important for recent history leading to this presentation but can also be important in some neurologic diseases, which recur or progress over time. In some neurologic contexts, timing can also refer to how symptoms vary by the time of day (eg, late-day fatigue and weakness in myasthenia gravis, sundowning in Alzheimer disease, and overnight headaches in brain tumor). Another component of timing is pace of symptom *onset* or how quickly the symptoms first began. Rapid onset of limb weakness within seconds would be expected for example in stroke, and is in contrast to slowly evolving clumsiness or weakness as may be seen in brain tumor, and an evolving weakness brought on during a multiple sclerosis attack becoming more apparent over the course of hours or a day. Particular attention should be paid to the onset of symptoms, the circumstances in which they occurred, and their subsequent evolution. Have any of the symptoms resolved? Have similar or different neurologic symptoms occurred previously?

Some neurologic diseases have overlapping clinical features, with similar onset but differ in manifestations at the time of onset as well as *duration*. Key examples are of seizures, strokes, and syncope, all of which are all abrupt in onset. Syncope has the briefest duration. There are usually sensations that warn of the impending loss of consciousness. Injuries to the face more common than other areas of the head because patients often pitch forward suddenly and uncontrollably when fainting. After fainting, the patient begins to recover consciousness in a minute or so. A seizure may or may not be preceded by warning symptoms, often enough so that a patient may ease themselves to a seat or the ground/floor. The seizure may be brief or protracted and is manifested by alteration of consciousness or by repetitive movements, stereotypical behavior, or abnormal sensations. Abrasions are common in seizure, typically due to an area of the body repetitively abrading a surface during the seizure. A stroke due to cerebral ischemia or hemorrhage strikes "out of the blue" and manifests as hemiparesis or other focal brain signs. The neurologic disorder that follows brain infarction may last briefly (transient ischemic attack), be permanent, or the patient may recover partially, or completely, in days or weeks. Sometimes, it is difficult to differentiate a transient ischemic attack from the postictal hemiparesis of a focal motor seizure, especially if imaging shows no lesion, and the seizure was not witnessed. Another syndrome of abrupt onset is subarachnoid hemorrhage, in which the patient is struck by a headache that is instantaneously severe and sometimes followed by loss of consciousness.

Symptoms of less than apoplectic onset may progress for hours (intoxication, infection, or subdural hematoma), days (Guillain-Barré syndrome), or longer (most tumors of the brain or spinal cord). The acute symptoms of increased intracranial pressure or brain herniation are sometimes superimposed on the slower progression of a brain tumor. Progressive symptoms of brain tumor may be punctuated by seizures. Heritable or degenerative diseases tend to progress slowly, becoming most severe only after years of increasing disability (eg, Parkinson disease, Alzheimer disease, essential tremor).

In chronic or recurring diseases, it is important to explore for *remissions* and *exacerbations*. These are characteristic of myasthenia gravis, multiple sclerosis, and some forms of peripheral neuropathy. Bouts of myasthenia tend to last for weeks at a time; episodes in multiple sclerosis may last only days in the first attacks and then tend to increase in duration and leave more permanent residual neurologic disability. Benign paroxysmal positional vertigo will have clusters of days with attacks, often most severe in the morning, with gradual improvement in severity of symptoms day by day, interspersed with weeks to months with no symptoms. Dementia with Lewy bodies is uniquely associated with fluctuations, whereby physical abilities (eg, parkinsonian features) and/or cognitive changes (ranging from lucency to confusion) are noticeable to patients or others on a day to day (or multiple day) basis, or within a day. Some diseases become progressively worse without remissions.

Some disorders characteristically occur in bouts that usually last minutes or hours but rarely longer. Periodic paralysis, migraine headache, cluster headaches, and narcolepsy are in this category. To recognize the significance of these differences in tempo, it is necessary to have some knowledge of the clinical features of the several disorders.

Quality of Subjective Experiences

The *quality* of the neurologic symptoms is perhaps the broadest of terms and comprise a wide array of features, often describable only by the patient for changes in sensation or by a careful observer when physical problems become apparent. In the context of a presentation of sensory loss, patients may report the quality of sensory changes in a range of terms from numbness to coldness. Similarly, pain is reported variably by terms including tingling (which may instead be noxious paresthesias) to burning, gnawing, aching, stabbing, or throbbing. One important quality

of a neurologic presentation is *severity*. That is, how apparent, severe, or debilitating are the symptoms and how someone may be functionally affected in their daily life. This can range from mild to profound and has relevance in a range of presentations such as weakness, headache, and cognitive abilities impacting functional independence. Also, related to timing, an important aspect of severity is to understand how quickly and over what time frame neurologic problems evolved to its most obvious or debilitating degree (a "peak" for pain or "nadir" for neurologic deficits). Moreover, it is important to know whether the problems remained at the same level of deficit consistently or improved in some fashion, and over what time this occurred.

Alleviating and Aggravating Factors

It is also important to identify contextual factors by which neurologic problems improve or worsen, sometimes termed *alleviating* or *aggravating* factors. Sleep deprivation, medical illness such as infection, and exposure to heat can aggravate neurologic symptoms, make them more apparent, or seem to cause older problems to recur. Among neurologic problems, pain disorders are especially worth exploring for factors, which may improve symptoms, such the impact of medications, circadian patterns, stress, and diet may impact headaches. In some cases, it is worth exploring inducing or inciting factors, which may bring about neurologic symptoms. For instance, in migraine, loud sounds, bright lights, strong smells, or motion may bring initiate or worsen headache symptoms. In some patients, epilepsy, ambient strobe lights may induce seizures.

Related Symptoms

Finally, it is important to explore for other *related symptoms*, which evolve in the context of a neurologic disease presentation or other contextual factors important in describing the initial course. Related symptoms may be neurologic or nonneurologic. In the context of stroke, exploring for other stroke-like episodes in the recent past would be important to potentially identify a stuttering or recurring course. Exploring for cardiac symptoms such as tachypalpitations suggestive of undiagnosed atrial fibrillation can help narrow the search for the etiology of a large territory and thus presumed cardioembolic stroke.

It may be of diagnostic importance to ask patients how long they have been having similar symptoms. Long-standing headache is more apt to be a migraine or tension headache, but headache of recent onset is likely to imply intracranial structural disease and should never be underestimated. Similarly, a seizure or drastic personality change for days or months implies the need for computed tomography, magnetic resonance imaging, and other studies to evaluate possible brain tumor or encephalopathy. If no such lesion is found or if seizures are uncontrolled for a long time, perhaps video-electroencephalographic monitoring should be carried out to determine the best drug therapy or surgical approach.

Behaviors Only Observable by Others

A corroborative informant is often an important resource in neurologic disease with a cerebral localization, particularly for neurologic symptoms for which the patient may be unaware. Patients with epilepsy may experience lapses of time, potentially representing periods of poor awareness or alternatively memory problems related to medication side effects. If possible, subtle observable behaviors in epilepsy may suggest automatisms or perceptions of cognitive disengagement or distancing during nonmotor seizures. Also in epilepsy, observed behaviors including the sequence of events leading to more obvious motor seizures can only be provided by observation, unless it has been recorded. In dementia, much of a cognitive history may need to be provided by others knowledgeable of the history and with reliable observation; some aged spouses may face their own memory problems and may require other persons to provide reliable information. Sleep disorders are a third category, which are best disclosed through observation of snoring, dream enactment, or limb movements. Sleep is often unobserved in persons living alone or without a bed partner or may be unrecognized if a bed partner is a sound sleeper. More obvious, overnight events such as falling out of bed (also due to dream enactment) or wandering (in dementia) may only come to attention once sentinel or catastrophic events occur such as injury during the activity.

Further Shaping the History and Differential

Age of the Patient

The symptoms and signs of a stroke may be virtually identical in a 10-year-old, a 25-year-old, and a 70-year-old patient, but the diagnostic implications are vastly different for each patient. Some brain tumors are more common in children, and others are more common in adults. Progressive paraparesis is more likely to be due to spinal cord tumor in a child, whereas in an adult, it is more likely to be due to multiple sclerosis. Focal seizures are less likely to be fixed in pattern and are less likely to indicate a specific structural brain lesion in a child than in an adult. Myopathic weakness of the legs in childhood is more likely to be caused by muscular dystrophy than polymyositis; the reverse is true in patients older than 25 years. Muscular dystrophy rarely begins after age 35 years. Multiple sclerosis rarely starts after age 55 years. Functional cognitive disorders are unlikely when neurologic symptoms start after age 50 years. These ages are somewhat arbitrary, but the point is that age is a consideration in some diagnoses.

Gender Specificity

Only a few diseases are gender specific. X-linked diseases (eg, Duchenne muscular dystrophy) occur only in boys or, rarely, in girls with chromosome disorders. Among young adults, autoimmune diseases are more likely to affect women, especially systemic lupus erythematosus and myasthenia gravis, although young men are also affected in some cases. Women are exposed to the neurologic complications of pregnancy and may be at increased risk for stroke because of oral contraceptives. More men than women are exposed to activities such as sports, which involve potential repetitive head injury.

Technology as an Assistive Tool

Technologic advances in patient monitoring, including wearable devices offer continuous data, which may be used in conjunction with the history. These include heart rate and telemetry, sleep, and diabetic monitoring devices. At this point, these tools largely serve to inform risk factors potentially contributing to neurologic presentations. Additional means of engaging technology in neurologic history include more observable and objective information, such as videos, which may capture a moment of impact leading to head injury now commonplace in

organized sports. Ambulatory electroencephalography (EEG) can be used in conjunction with epilepsy histories, should an event be captured while an EEG is being worn (EEG is discussed further in Chapter 26).

Presymptomatic or Asymptomatic Genetic Variants

In recent years, one of the more transformative changes seen in medicine and neurology has been the rapid growth of genetic testing, including direct to consumer marketing, which often occurs without anticipatory guidance of a neurologist or other physician. Whole genome sequencing can also identify rare genetic sequences or variants of uncertain significance within genes associated with various neurologic diseases. Patients are increasingly presenting to offices with test results in hand, seeking understanding for their potential meaningfulness, and potential treatment options. In such cases, clinicians are tasked with looking for problems, rather than responding to a concern. This somewhat reverse approach to history taking has been a challenge for years prior to more widespread availability of genetic testing, such as patients facing a strong family history of neurologic disease but unaware of their own genetic status or even that of other family members. Internet searches undertaken by patients in advance of initial assessments can complicate matters further whereby patients learn of what potential symptoms to expect and may become fixated on these even when nonexistent. Although controlled studies of disclosure of genetic status in cognitive disorders have not suggested major differences in cognitive profiles by genetic status, some patients can become fixated on genetic test results, even when seemingly inconsequential or without known neurologic implications.

Neurologic Symptoms in Nonneurologic Disease

Unexplained neurologic symptoms are common in neurologic practice, comprising upward of one-third of outpatients seen in large academic centers. One of the essential roles of the neurologist is to not just identify neurologic disorders but to exclude patients presenting with symptoms, which could potentially be neurogenic but inevitably have a basis of explanation in another organ system, or have a functional basis (sometimes referred to as *psychogenic*). Nonetheless, these patients warrant full exploration of history as understanding the basis for interpretation by the patient and other clinicians as that of a neurologic disorder could inform complementary treatment strategies.

Problem-Based History

In addition to the framework described earlier, another helpful approach is to consider how the patient may fit into the broad framework of neurologic problems, further discussed in the following text. Perhaps unique to neurology is the relatively broad array of neurologic symptoms, which can occur, given that neurologic diseases can present and affect the entire human body and ranges in cause from molecular and microscopic peripheral disorders to space-occupying brain disease. A summary of key features and red flags for "can't miss" diagnoses are included in Table 3.2, covering common neurologic problems. This framework aims to structure the approach to the patient, particularly because the differential becomes narrowed following the initial review of the history.

PAST MEDICAL, PSYCHIATRIC, AND SURGICAL HISTORIES

It is always important to know whether there is any systemic disease in the patient's background. Common disorders, such as hypertensive vascular disease or diabetes mellitus, may be discovered for the first time when the patient is examined for neurologic symptoms. However, because they are common, these two disorders may be merely coincidental in this and other diseases. If the patient is known to have a carcinoma, especially if weight loss is present, metastatic disease is assumed to be the basis of neurologic symptoms until proven otherwise. If the patient is taking certain medications, the possibility of intoxication must be considered. Cutaneous signs may point to neurologic complications of von Recklinghausen disease or other phakomatoses or may suggest lupus erythematosus or some other systemic disease. Recent vaccinations and possible infections (including human immunodeficiency virus history and testing) are important to explore for both reactive and autoimmune disorders as well as active infection explaining the current presentation.

NEUROLOGIC REVIEW OF SYSTEMS

Although a well-rounded history should emerge following the steps described earlier, a structured and complete review of neurologic systems can help to assure that subtle neurologic symptoms are not missed. In some cases, subtle symptoms may be overlooked even though they represent a more substantial burden of disease. For example, a patient with metastatic brain cancer may present with seizure due to a small occipital metastasis, later discovered to have a much larger frontal mass causing more subtle personality change. Broadly speaking, a neurologic review of systems should include at least a cursory review of psychiatric symptoms (particularly mood changes or personality changes), cognitive symptoms (most often relatable as "memory changes"), changes in smell or taste perceptions, visual disturbances or loss (beyond just need for corrective lenses), changes in sensation anywhere in the body, speech or swallowing problems, motor symptoms (weakness, imbalance, tremor, or falls), and autonomic symptoms (light-headedness/dizziness, constipation, urination, the presence of dry eyes, sexual dysfunction). The neurologic review of systems can also be problem focused around the presumed diagnosis, such as exploring for common neurologic syndromes in patients with presumed multiple sclerosis (eg, diplopia, hemiparesis, hemisensory symptoms, mobility and gait disturbance, incontinence, and cognitive impairment), as discussed further in Table 3.2.

SOCIAL HISTORY

The "social history" has broad relevance in neurology, particularly in how it captures substantive life experiences. Important elements include educational and occupation histories (including military experience), immigration and acculturation, primary and secondary languages because these particularly can have bearing on interpretation of cognitive and neuropsychological testing. In the United States and elsewhere, life experiences tied to race and ethnicity more broadly fit into social determinants

TABLE 3.2 Neurologic Histories Based on Common Neurologic Problems

Neurologic Problem	Common Features to Explore	Concerning Features
Dizziness	• Age and symptoms at onset • Type of dizziness (vertigo, imbalance, orthostatic, poorly categorized) • Course: periodic/recurrent vs progressive • Precipitating factors including head/body movement • Frequency and intensity of events • Treatment history and response, including nonpharmacologic treatment (canalith repositioning maneuvers) • Associated features including pain and sensory changes, focal cranial weakness, vision and hearing changes, changes in alertness, autonomic features, and headache • Impact on daily activities • Profession/vocation and traumatic exposures associated with unusual positions posing risk for position vertigo or cervical dissection	• Headache • Cranial neuralgia • Focal neurologic signal • Diplopia • Progressive pulsatile tinnitus or deafness • Hoarseness or other voice/speech changes • Catastrophic vertiginous attacks leading to injury
Headache LEVEL 1[2]	• Age at onset • Headache quality (location, symptoms at onset, timing, and duration) • Frequency and intensity • Severity • Associated visual, visceral, and cognitive symptoms during the headache • Autonomic features • Hypersensitivities (light, sound, smells, scalp) • Precipitating factors (diet, sleep, stress, menstruation, head position, activities) • Medication response • Behavioral response (avoidance of noxious stimuli) • Functional impact of frequent headaches	• New-onset symptoms • Worsening/new symptoms in patient with a preexistent headache syndrome • Age >50 y • Abrupt onset • Positional features • Constitutional symptoms to suggest systemic illness • Focal neurologic features • Mental status changes
Back pain	• Onset and chronicity • Location • Quality including severity, intensity, duration, and associated features • Any patterns of radiation, weakness, and numbness • Precipitating and alleviating factors • Urination and sexual function • Strength, balance, and falls • History of immunocompromise, infection, malignancy, or suggestive constitutional symptoms • Psychological history as a possible contributor, including mood disorders, stressors including ongoing litigation, and potential secondary gain • Exploration for chronic trauma including manual occupational history	• Constitutional symptoms • Fever • Focal neurologic deficits • Progressive syndrome • Older age
Demyelinating disease	• Age at onset of first possible neurologic symptoms • Nature of onset, duration, and progression of each event • Review for current or prior common demyelinating neurologic syndromes: optic neuritis, internuclear ophthalmoplegia, hemiparesis, hemisensory syndrome, mobility and gait disturbance, incontinence, cognitive impairment. • Precipitating factors (Uhthoff and Lhermitte phenomena) • Treatment history and response including flares and prevention as well as compliance • Other autoimmune history, including undiagnosed (dermatologic, arthropathies, solid organ disease, myalgia) • Family history of autoimmune disease	• Rapid progression • Poor response to therapy • Severe burden of illness, particularly if multifocal and without tissue-based diagnosis • Systemic features
Dementia	• Explore for impact on cognitive domains (memory, visuospatial function, language, executive function, processing speed). • Duration, pace/speed, and course of changes (including progressive vs stepwise decline) • Psychiatric features (mood, sleep disturbance, psychotic symptoms, including the frequency, timing, and severity of each) • Fluctuating daily vs progressive course • Motoric changes to suggest parkinsonism (see "Movement Disorders" in this table) • Urination • Focal neurologic features • Medication history and response (particularly paradoxical response to antipsychotics) • Past history of sleep disturbance (sleep apnea), infection (syphilis or HIV), traumatic brain injury, or alcoholism • Educational, professional, vocational, and leisure history exploring for expected cognitive abilities • Psychosocial and caregiver support	• Rapid onset or progression • Focal including unilateral features • Seizures • Impaired attention to suggest delirium • Incomplete psychosocial support or observation posing immediate risk for catastrophic injury to self or others (wandering, falls, household fires, driving)

TABLE 3.2 Neurologic Histories Based on Common Neurologic Problems *(continued)*

Neurologic Problem	Common Features to Explore	Concerning Features
Movement disorders	• Age at onset and progression • Changes in handwriting, cutting food, and impairment with other dexterous movements • Slowness • Gait changes and tripping/falling hazards (slower pace, imbalance, and falls) • Tremors, fidgeting (chorea), jerking (myoclonus), and other observable adventitious movements • Voice changes • Dream enactment and other sleep disorders • Cognitive impairment • Autonomic dysfunction • Medication history and responses • Medical history for hepatic and renal disease, parathyroid disorders, diabetes, HIV, cardiac disease, and syncope • Explore for potential exposure to agricultural pesticides, heavy metals, and substance abuse. • Detailed family history for movement disorders and other neurodegenerative disorders • Identify social support network.	• Young onset • Rapid progression • Poor medication responsiveness • Gait instability and falls • Dysphagia and choking • Cognitive impairment or behavioral changes • Incomplete monitoring and support suggesting emerging risk for catastrophic injury • Constitutional symptoms, toxic exposure or recent febrile illness immediately preceding onset
Peripheral neuropathy and neuromuscular disorders	• Localization and pattern of primary features: laterality, proximal vs distal, diffuse vs focal/segmental • Age at onset • Onset, progression, and course • Recovery vs cumulative burden • Determination of presence and severity of sensory and motor symptoms • Spontaneous sensory symptom review: paresthesias, allodynia, dysesthesia, hyperalgesia, hyperpathia, spontaneous pain • Motor symptoms: weakness, speech, swallowing, diplopia, diurnal variability, influence of activity, fasciculations, cramps/pain, balance • Medical history for systemic disease: cardiac and other autonomic symptoms, recent infections, vaccinations, rash, and travel	• Constitutional symptoms • Rapidly progressive symptoms • Dysphagia or dysarthria suggesting motor neuron disease
Diseases of the spinal cord	• Onset, course, and precipitating factors • Precipitating factors, including trauma or repetitive physically demanding activities • Aggravating/alleviating factors or positions leading to motor, sensory, and pain symptoms • With pain, explore quality, radiating and radicular features, and provocative factors • Location, severity, and functional impact • Bowel, bladder, and sexual function • Perineal sensation • Medical history including malignancy, infection, immunosuppression, and recent spinal instrumentation	• Acute presentation for any disorder • Any presentation suggesting spinal cord localization • Urinary retention or loss of bowel/bladder function • Pain suggesting central spinal, cauda equina, or conus medullaris localization • Respiratory compromise suggesting diaphragmatic weakness • Autonomic dysregulation
Central nervous system tumor	• New-onset headache, seizures, cognitive decline (as reviewed in this table) • Loss of consciousness • Focal or multifocal neurologic symptoms	• New headache or unusual headaches for patient • Positional component suggesting increased intracranial pressure • Constitutional or general symptoms suggesting metastatic disease
Infections of the nervous system	• Onset, progression, and duration • Headache • Fever • Neck pain • Change in alertness • Focal neurologic deficits • Worsening or new back pain • Chronic risk factors for neurologic infection: immunosuppression, head trauma, recent ENT or neurosurgical instrumentation, sick contacts or travel to endemic areas of suspected infection, IV drug abuse, • ongoing systemic infection	• Fever • Rapid onset of symptoms • Decreased or decreasing level of alertness • Possible or obvious seizures • Hypotension

(table continues on page 22)

TABLE 3.2 Neurologic Histories Based on Common Neurologic Problems *(continued)*

Neurologic Problem	Common Features to Explore	Concerning Features
Seizures	• Age at onset • Semiology of seizures (localization/onset including "aura," progression of observable features, subtle features) • Timing, frequency, and duration of seizures • Symptoms known to be associated with various epilepsy syndromes • Associated cognitive and other neurologic disorders. • Explore for seizure mimics (headache, stroke, syncope). • Anticonvulsant medication history including responses (control, side effects, and compliance) • Precipitating factors (fever, medication, sleep deprivation, photic stimulation) • Risk factors for focal brain injury throughout a lifespan • Chronic medical problems (metabolic, psychiatric, malignant, infections) • Psychosocial impact of recurrent seizures • Family history	• New-onset seizures • Worsening seizure control with established epilepsy • Constitutional symptoms • Interictal features to suggest structural brain disease (headaches, focal symptoms, cognitive, or personality change)
Stroke	• Timing and duration, including last observed normal point in time • Contraindications to acute thrombolytic care and/or thrombectomy • Etiology and risk factors for cardioembolic, thromboembolic, small vessel, venous, inflammatory, and genetic syndromes, including compliance with therapy for known risk factors • Localization based on syndromes with known vascular territory • Stroke mimics or other neurologic features (headache, stroke, seizures, known recent history of severe hypoglycemia)	• Suggestion of large territory or posterior fossa localization, suggesting risk for immediate worsening • Rapid clinical worsening • Hemodynamic instability
Stupor and coma	• Last known normal • Potential precipitating factors or any known subtle recent symptoms • History of loss of consciousness • Constitutional symptoms • History of alcohol abuse • Family history, particularly for aneurysms, polycystic kidney disease, or connective tissue disease	• Recurrent seizures or status epilepticus • Suggestion of herniation syndrome or other indicators of critical intracranial pressure • Apnea

Abbreviations: ENT, ear, nose, and throat; HIV, human immunodeficiency virus; IV, intravenous.

of health and likely serve as surrogates for a complex and highly variable life experiences tied to income, employment, job and food security, diet, systemic racism and other sources of stress, physical health, and access to health care. Many of these factors interrelate. Often, many of these elements are challenging to discover or are not revealed in brief encounters.

Although alcohol, tobacco, and substance use/abuse are often recorded within the social history, their inclusion may be more relevant in the medical history, particularly if it has been chronically present or likely causal to various health conditions. Accurate identification of acute/recent use may be particularly relevant in neurologic patients presenting with acute cognitive disorders such as delirium, stroke, and ataxia. Some synthetic substances abused may not be detectable and require a definitively derived history.

Travel and Occupational History

A review of recent travel can be instructive for potential exposure to potentially rare or uncommon infections. It may also be the case that infections acquired while traveling are common yet uncommonly seen by the evaluating physician once the patient has returned home. Travel can also lead to preventative therapies used in advance of exposure to endemic infections, and these treatments may be associated with neurologic or psychiatric side effects. Travel can also be important in exploring for exposures to prolonged positions, such as deep vein thrombosis associated with long airline travel (and a risk factor in paradoxical stroke). Travel can also reveal subtle or unrecognized cognitive disorders, when a patient is placed in unfamiliar or confined locations, or subject to circadian disturbances leading to unexpected or severe symptoms of jetlag.

Occupational and vocational exposures as well as hobbies are important to explore given potential relevance to neurologic disorders. Toxic exposures are found in some occupations or hobbies (welders and chemists among others). Adverse ergonomics may be common with some hobbies (video gaming), occupations (computer use, manual laborers), or habituations (assumed posture while seated) and lead to a host of problems due to focal compression, including sciatica and lumbar spondylosis, fibular neuropathy, carpal tunnel syndrome, cervicalgia and cervical spinal stenosis, and ulnar neuropathy at the olecranon.

Dietary and Nutritional History

Diet and nutrition are infrequently explored in practice but can be informative in revealing nutritional deficiencies and food avoidant behaviors. Patients with developmental disorders and autism may be especially susceptible to unrecognized progressive restriction in diet and may further manifest with atypical or challenging symptoms. Persons subject to displacement, famine, or marginalization are especially susceptible to extrinsically narrowed diets due to access, due to finances, or general access food in order to satisfy caloric needs as well as a full array of micronutrients including vitamins with known neurologic micronutrient deficiency syndromes. Persons at risk for malabsorption or malnutrition including anorexia/bulimia, cystic fibrosis, ulcerative colitis/Crohn disease, and irritable bowel disease may be especially susceptible to vitamin deficiencies. Although uncommon, persons having undergone bariatric surgery may develop

micronutrient deficiencies, either due to noncompliance with vitamins taken chronically postoperatively, or other postoperative coincidental enteropathy and malabsorption syndromes. Patients with autonomic disease can have impaired gut motility and secondarily diminished appetite due to early satiety. In dementia, meals are often forgotten, and some treatments, particularly cholinesterase inhibitors, have anorexia as a potential side effect.

FAMILY HISTORY

Family history can be revealing in a broad array of neurologic diseases and should be fully explored in each patient presenting with neurologic disease. As covered further in Chapter 35, a familial basis of disease is common in nearly all neurologic disorders but may range in relevance to individual patients. Some disorders are genetically complex and common and may influence perceptions of how disease may occur. This is particularly the case with migraine and other headache disorders, which comprise upward of half of outpatient neurologic practices.

Even when perceived as negative or "noncontributory" (a nearly universally inappropriate shortcut, which should be stricken from a clinician's vocabulary) inclusion of vital status, ages of death, birth order within a sibship, and common medical problems for at least first degree family members should be recorded. For some patients, family history in remote family members may raise their concern and be the reason for presentation when asymptomatic. Some neurologic diseases or their risk factors have been historically associated exclusive with certain race-ethnic groups, but these notions are quickly becoming antiquated. This change reflects a number of factors including human globalization with interracial relationships and offspring, and earlier errors in case ascertainment when certain populations were studied without appropriate comparison to other populations. Nonetheless, there remain some neurologic diseases and founder mutations, which make them more likely in certain populations, yet not exclusive to them.

DIAGNOSTIC SYNTHESIS

As detailed in the introduction, during the course of eliciting the neurologic history, diagnostic reasoning often leads the questioning. At the conclusion of all the steps of the neurologic history, the examiner should have a fairly well-formed differential diagnosis, as well as leading considerations and a presumably brief list of "can't miss" diagnoses. At this point, reasoning has usually fairly formed into a true diagnostic synthesis, which may bear some review both internally and with the patient. The next step is most often the neurologic examination, which offers opportunities to confirm and refute this synthesis and is reviewed in the next chapter.

The Neurologic Examination 4

James M. Noble

KEY POINTS

1. Combined with the neurologic history, the exam is a powerful tool to help shape initial steps of the diagnostic workup and tailor management.
2. An organized approach to each patient exam, informed by history and other exam findings, is an efficient way to establish localization.
3. Screening and comprehensive neurologic examinations have been proposed and should be used appropriately, tailored to the clinical context.
4. Key components include cognitive or mental status testing, followed by cranial nerve, motor, reflex, coordination, sensation, and gait exams.
5. Additional special tests and techniques are tailored to the patient's presumed diagnosis or working differential diagnosis.

INTRODUCTION

Of all the chapters presented in this book, the one most likely to remain nearly 100% relevant, if not also accurate, decades from now is that of the neurologic examination. New handheld, bedside, and other point of care tools continue to inform and will further shape the interpretation of the examination over time. Teleneurology and other virtual assessment tools have changed the way in which doctors and other clinicians engage with their patients and can be highly informative when an in-person assessment is not possible. The general utility of and approach to the neurologic examination have not substantially changed for decades and are unlikely to substantially differ over a trainee's career.

An exhaustive description of all potential tests comprising the comprehensive neurologic examination is beyond the scope of this chapter. Instead, the intent is to provide a set of guiding principles and essential techniques on which the neurologic examination can be built to support, augment, or refute findings suggested by the neurologic history. A thorough neurologic history and examination are designed to accurately localize neurologic dysfunction and develop a differential diagnosis of the most likely disease processes. The history and physical should be used in a complementary manner rather than as stand-alone devices. As detailed in Chapter 3, with the patient or family members as informants and the physician as historian, the neurologic history should be a logical, linear story told such that the history leads sensibly into the examination, without many surprises to the examiner or another physician hearing about the encounter. Furthermore, the neurologic examination may lead to a reassessment of the accuracy of the history or identifying new or additional collateral sources, particularly if memory problems are identified.

This chapter should be used in close conjunction with the guidelines for developing the neurologic history that are presented in Chapter 3. Moreover, the primary goals of this chapter regard the approach to most adult patients seen in inpatient and outpatient settings, with the exception being the critically ill neurologic patient. The approach to the stupor and coma examination is presented in Chapter 19. Key features of the infant and child neurologic examinations are covered in the Pediatric Neurology section.

Setting Goals of Examination Versus Neurologic Tests

As is the case in many professions, there are likely as many ways to accomplish an examination as there are examiners performing the examination itself. However, some approaches may be far more efficient, understandable, and sensible than others. There are numerous neurologic examination techniques known, sufficient to comprise a substantial book, let alone a single chapter.

The approach presented here is intended to demystify the reasons for and the methods by which a comprehensive neurologic examination is accomplished. Regardless of one's eventual scope of practice, neurologic or otherwise, all clinicians must have sufficient confidence, skill level, and knowledge base to begin to develop a proficient neurologic examination for each context it requires. There must be a balance between the expectation of a comprehensive examination that neurologists can accomplish, and a focused or screening neurologic examination all clinicians can perform when assessing for a potential neurologic emergency, life-threatening diagnosis, or treatable problem. Elements suggested to be included in comprehensive and screening neurologic examinations are provided in Table 4.1. Also, some elements of the neurologic examination may be expanded in specialty practices. Examples include a more involved assessment of behavior and cognition (behavioral neurology), focused assessment of movement and tremor (movement disorders), sensory and motor examinations (neuromuscular disorders), and provocative extra-ocular maneuvers (neuro-ophthalmology and sports neurology practices).

A Top-Down Approach

The manner in which the neurologic examination should be presented follows a structured approach that facilitates a complete and comprehensive neurologic examination. Anatomically and generally speaking, this follows a "top-down" approach, which begins with the mental status examination and cranial nerve examination at the top with the head, followed by the body including motor and deep tendon reflex examinations, followed

TABLE 4.1 The Neurologic Exam[a]

Comprehensive	Screening
Mental Status	
Level of alertness	Level of alertness
Language function (fluency, comprehension, repetition, and naming)	Appropriateness of responses
Memory (short- and long-term)	Orientation to date and place
Calculation	—
Visuospatial processing	—
Abstract reasoning	—
Cranial Nerves	
Vision (visual fields, visual acuity, and funduscopic examination)	Visual acuity
Pupillary light reflex	Pupillary light reflex
Eye movements	Eye movements
Facial sensation	—
Facial strength (muscles of facial expression and muscles of facial expression)	Facial strength (smile, eye closure)
Hearing	Hearing
Palatal movement	—
Speech	Speech
Neck movements (head rotation, shoulder elevation)	—
Tongue movement	—
Motor Function	
Gait (casual, on toes, on heels, and tandem gait)	Gait (casual, tandem)
Coordination (fine finger movements, rapid alternating movements, finger-to-nose, and heel-to-shin)	Coordination (fine finger movements, finger-to-nose)
Involuntary movements	Involuntary movements
Pronator drift	—
Tone (resistance to passive manipulation)	—
Bulk	—
Strength (shoulder abduction, elbow flexion/extension, wrist flexion/extension, finger flexion/extension/abduction, hip flexion/extension, knee flexion/extension, ankle dorsiflexion/plantar flexion)	Strength (shoulder abduction, elbow extension, wrist extension, finger abduction, hip flexion, knee flexion, ankle dorsiflexion)
Reflexes	
Deep tendon reflexes (biceps, triceps, brachioradialis, patellar, Achilles)	Deep tendon reflexes (biceps, patellar, Achilles)
Plantar responses	Plantar responses
Sensation	
Light touch	One modality at toes—can be light touch, pain/temperature, or proprioception
Pain or temperature	—
Proprioception	—
Vibration	—

by sensory and coordination exams, and finally gait. Although it may be tempting to approach the neurologic examination in a narrow or symptom-focused manner, this method introduces the risk of unintentionally forgoing an essential element of the neurologic examination and missing a diagnosis. This approach is also designed to allow for an efficient first-pass assessment, which can be followed by more focused, detailed, and refined examination based on relevant initial findings.

Helping Your Patient Through the Neurologic Examination

Some patients undergoing their first formal neurologic examination may describe its unexpected thoroughness and that some of its elements are even strange. Perhaps related to this, some patients may unintentionally embellish the examination or even provide nonsensical physical examination responses. In such cases, it may be helpful to tell the patient very specifically what is going

to be done as well as the expected outcome or finding, particularly when a normal examination is expected based on a benign relevant history. On the other hand, it may be more worthwhile to provide no instructions to patients with functional disorders who are also prone to purposeful embellishment or feigned signs. One may also repeat some elements of the neurologic examination after describing the expected findings to the patient.

Soft Versus Hard Neurologic Examination Findings

In some cases, the examiner may be inclined to search unnecessarily for an abnormality on neurologic examination based on history provided or alternatively identify a subtle unexpected finding referred to as a "soft" neurologic sign. Common soft findings include facial asymmetries, a previously unrecognized strabismus persisting into adulthood, imperfect memory, and balance problems; these and others may worsen with advancing age without necessarily being pathologic. Slight asymmetries, particularly in the face, are commonly found during neurologic examination in normal individuals and likely do not hold much clinical relevance. Soft neurologic signs including poor motor coordination, sensory perception, and motor sequencing may occur in as much as half of all healthy individuals. Unilateral subtle motor coordination differences often reflect dominant versus nondominant side abilities. Understanding when to strongly consider a finding, simply record it, or to discard it altogether may require the judgment of a skilled examiner to cautiously interpret each finding. However, by approaching the neurologic examination with a clear sense of the likely localization based on the history, interpretation of soft signs can become less challenging. When findings are found in isolation, particularly without a clear connection to the history, it may be justifiable to recognize and record the finding but not necessarily prioritize the finding when synthesizing a diagnosis. When finding a soft sign, its relevance can often be determined by repeating the test, clarifying or asking additional history, or performing additional neurologic examination techniques to determine whether it is found in isolation or relates to others on exam.

Descriptions Versus Impressions

Whenever possible, a description of neurologic findings should be included in the examination rather than the synthesis of the findings themselves. Changes in the neurologic examination day to day can be remarkably subtle, and only a descriptive neurologic examination may reveal such changes and sometimes only in retrospect. For example, a patient may be described on a series of examinations by different examiners to be lethargic; yet, substantially different levels of stimulus are required to result in the same response from the patient, ranging from light tactile to verbal stimuli to other more rigorous stimuli applied yet inadequately described. Such a failure to accurately describe the patient, particularly in an era increasingly reliant on effective care transitions, can jeopardize true understanding of neurologic disease progression in both inpatient and outpatient practices.

Positioning the Patient (and Examiner)

Appropriately positioning the patient and the examiner is an important first step in many aspects of the neurologic examination and is described in each of the relevant sections in the following text. Positioning of the patient and the examiner is important throughout the patient encounter, including initial moments of a patient encounter when developing patient trust and rapport. At the bedside, correct position with each component of the neurologic examination is essential in both effective and efficient performance and interpretation of the neurologic examination. Positioning is most relevant not only to assessment of visual fields, funduscopy, strength, and deep tendon reflexes but also during times of potential injury during provocative or potentially risky elements of the examination to the patient, such as pull testing for assessing postural stability, or even when standing a patient affected by frailty or imbalance suggested in the history or during gross inspection. Appropriate positioning is especially important when assessing for movements, which may occur at rest. For example, rest tremor is best observed in relaxed or neutral position such as resting the hands in the lap, upright with arms flexed.

Careful Observation and Examination Interpretation

Making a judgment about the presence or absence of a neurologic finding is an essential skill to interpreting the examination. Determining or judging normative or expected responses on the neurologic examination helps to refine findings further and likely follows experience with performing examinations on many of patients, ranging in age and variety of problems, over many years. Interpreting findings may also be informed by sociodemographic factors, particularly the cognitive examination.

After gaining sufficient experience to appreciate the range of normal examination findings, ranging from funduscopy to gait to behavior, an examiner can begin to dissect a subtly abnormal neurologic examination into its principal components. Although a specific diagnosis may be hard to determine, particularly among patients with complicated history, a dissection of abnormal findings on the neurologic examination, used in conjunction with the history, can facilitate localization and diagnostic approach.

Sometimes, despite best efforts, a complete neurologic examination may not be possible. Aside from the unique context of the coma patient, patients with cognitive impairment or agitation, or other psychiatric problems may not be able to comply with many elements of the formal neurologic examination. Much can be learned by careful observation, even from afar or remotely, including behavioral interpersonal interactions; visual fields through how the patient interacts with the environment; language and speech through conversation; and limb, trunk, and facial purposeful and involuntary movements and coordination through observation of movements while taking a history.

THE PATIENT EXAMINATION

General Medical Examination

Any patient with concern for a neurologic disease should be evaluated with a comprehensive general medical examination at least once in the course of their initial neurologic assessment. However, it is typically the case that a relatively brief overview of the general medical examination will be included in any neurologic case presentation with only the elements most germane to the neurologic diagnosis presented. For example,

examination for cardiac and carotid auscultation should be performed for a patient presenting with stroke, and skin should be assessed for rash in a patient presenting with proximal myopathy.

However, each patient should have a complete and accurate description of the general impression—the essence of the strong first impression each patient may have provided to the examiner. Specific points to mention may include general appearing of wellness, nourishment, habitus, manner of dress, or other related elements. Some of these elements may be reinforced in the mental status examination.

Mental Status Examination

In contrast to other elements of the neurologic examination, the mental status examination is composed of a potentially variable set of tasks tailored to each patient. Rather than beginning with the prespecified set of neurologic examination tasks, a far preferable approach is one that aims to develop a description of the function of the cognitive domains based on a set of often interdependent tests. It is difficult, if not impossible, to find any single test that can comprise and completely describe an entire neuropsychological cognitive domain. Instead, many tests map to several cognitive domains and vice versa. Conceptually, it is well-known that cognitive functions are highly interrelated functionally and anatomically, with the principal components of interest on examination representable as Venn diagrams (Fig. 4.1). These

FIGURE 4.1 Conceptual framework for the mental status examination and interpretation. Each of the five principal cognitive domains (language, memory, visuospatial, processing speed, and executive function) is drawn from a series of tests comprising the mental status examination. Relative strengths and weaknesses in each domain may be inferred based on a series of related tests, which map potentially to several domains but taken together can potentially identify one or more domains of impairment. The interpretation of each abnormality must be considered within the context of each test, including normative information if known. The relative function of each domain is likely influenced by and superimposed on crystallized knowledge, which conceptually summarizes education, life experiences, and cognitive reserve.

can broadly be broken down into domains of language, memory, attention and executive function, visuospatial function, and processing speed. Predicated on each of these is that the patient has a sufficient level of consciousness in order to participate in the examination.

There are several reasons that the neurologic examination includes a standardized mental status assessment. First, any standardized cognitive screening examination will often have been developed in the context of hundreds, if not thousands, of applications and multiple social economic and cultural contexts, making its interpretation more generalizable. Second, at the level of the examiner, use of the same examination repeatedly may give the examiner greater confidence in examination skill and interpretation based on a learned experience of typical or expected responses developed over the course of giving the same test in multiple clinical contexts. Third, most standardized mental status examinations allow for a hierarchical approach to understanding someone's cognitive abilities. For instance, for a task of delayed recall, it is important to understand not only what a patient can freely recall but also what the patient may recognize either through the contextual or categorical clue given for recognition tasks or subsequently through list of forced choices. Using a sequential, hierarchical approach to assessing memory abilities allows for determination of free word retrieval (presumably a harder response) versus recognition (by choices), which are thought to be independent of registration tasks. Finally, serial assessments of an individual patient may require adjustment of examination techniques to avoid the potential effects of learning or practice.

Many caveats apply to interpreting the mental status examination and thus require understanding and how it is devised for each patient, particularly how it is tailored to each cultural context. For instance, education and lifetime cognitive abilities play a strong role in one's ability to interpret both normal and abnormal mental status examination findings. Prior to each mental status examination, developed within social history must be a clear sense of someone's educational history, literacy, and thus likely expected performance on mental status testing. When interpreting formal neuropsychological testing, two norms are considered: the person's premorbid intellectual capacity as determined by intelligence quotient and professional accomplishments as well as comparison to normative values based on peer performance matched to age, education, and potentially primary language.

It is important during the mental status examination not only to record whether or not the patient correctly answers the question but also to record the actual response itself. Much can be learned through some elements of the mental status examination, which can, to some degree, be influenced by complex factors including mood. For instance, a patient may be considered to be disoriented to time and place through simple scoring, but when review of the actual answers suggests an exactly wrong response to every single question (including nonsensical dates, often in the future), it might suggest an element of feigned or embellished neurologic examination.

Determining Alertness

The entirety of the formal mental status testing is predicated on a patient being fully awake, alert, and able to engage the examiner. Presuming this is the case, the neurologic examination as described in the following section is relevant in such a patient. Determining a depressed level of alertness is described in Chapter 19 as it relates to the examination of coma and the brainstem examination.

Language

Language is composed of seven principal components: (1) fluency, (2) prosody, (3) repetition, (4) naming, (5) comprehension, (6) reading, and (7) writing. A language examination is not complete without each of the seven elements. The pattern of dysfunction related to these seven components allows the neurologist to diagnose and classify all types of aphasia (Table 4.2).

Fluency and prosody can often be determined through development of the neurologic history before turning to formal examination. Prosody is the musical component of language, the singsong nature, and cadence that allows one to understand the nature of a stated expression. For example, prosody allows one to discern when a declarative sentence is stated versus a question. In contrast to normal prosody, aprosodic language may be identified among patients with major neuropsychiatric disorders including schizophrenia or in patients with advanced or untreated Parkinson disease. Fluency is a quality of speech pertaining to the ability of a patient to express himself or herself without hesitation or disruption spontaneously as well as during formal testing. Dysfluent speech may have hallmarks of patient frustration or an unexpected halting pattern, such as that seen in a suddenly acquired Broca area stroke, or progressively developed in a patient with the progressive nonfluent aphasia form of frontotemporal dementia. Dysfluent speech is distinct from thought blocking, which is described within the elements of psychiatric examination.

Repetition may be assessed by asking a patient to repeat a simple, understandable phrase and further tested by a longer more complex sentence if the history and examination warrant further exploration. When such a phrase cannot be repeated, repetition of single words should be attempted.

Naming also should be approached in a hierarchical manner when testing knowledge of names of presented objects and virtual pictures. Standard images/figures comprise most neurologic screening examinations but differ among each exam. Objects to be named should be ubiquitous, well-known to the patient, and have elements that offer an opportunity to test parts and not just the sum of the object. This approach may reveal difficulty in describing low-frequency relative to high-frequency words, as is often seen in disorders like Alzheimer disease. In addition, the naming examination may be tailored to the patient for objects well-known in the context of life experience or profession, such as images of a set of carpenter's tools. A number of forms of specific categorical dysnomic aphasias are known to exist, such as color dysnomia, and should be tested in the appropriate clinical context.

Comprehension is often tested as a three-step command. As with a memory task, the patient should be prompted to expect the task rather than occurring as a surprise. Numerous three-step commands have been published but should be easily understandable, contextually appropriate, and whenever possible use commonly available objects so that the same task can be repeated by a single examiner in multiple clinical contexts.

Reading testing begins with a patient reading a simple sentence aloud and offers an opportunity to test for comprehension by having the patient act on the sentence provided. Should a patient have difficulty reading a sentence (eg, "Close your eyes."), then the examiner should move on to simple phrase or a single word if the phrase cannot be read. In a similar approach, writing should begin with an instruction for the patient to write a complete sentence. If this cannot be accomplished, the patient should be asked to write a simple dictated sentence. If this is further not possible, the patient should be asked to write or sign his or her name, although this principally tests for praxis or dysgraphia. Such highly learned written tasks, and even a signature, likely localize to the nondominant frontal lobe as a procedural motor task, or engram, rather than a function of spontaneous written language.

Memory Testing

Differing definitions of working, short-, and long-term memory exist, are often used inappropriately in colloquial examination and presentations, and may have differing meanings depending on the person reviewing the examination described by others. A formal description of various forms of memory is provided in summary in Table 31.2. Working memory is generally considered to be the online or in-the-moment memory, such as what may be used when repeating a series of unrelated words or number sequence. Short-term memory involves testing a set of ideas registered with the patient and specifically queried by the examiner after a delay of several minutes. Items not freely recalled but instead recognized from a list (recognition) can be

TABLE 4.2 Types of Aphasia

Aphasia Subtype	Fluency	Comprehension	Repetition	Localization
Expressive (motor, Broca)	Effortful speech with paraphasic errors[a] and agrammatism[b]; mutism in severe cases	Normal	Impaired[c]	Frontal opercular region of inferior frontal gyrus (Broca area) in the dominant hemisphere
Receptive (sensory, Wernicke)	Fluent speech, mostly nonsensical in content; frequent paraphasic errors	Impaired	Impaired[c]	Posterior-superior temporal region (Wernicke area) in the dominant hemisphere
Global aphasia (combination of expressive and receptive)	Effortful speech with paraphasic errors[a] and agrammatism[b]; mutism in severe cases	Impaired	Impaired[c]	Both inferior frontal gyrus and posterior-superior temporal region in the dominant hemisphere
Conduction aphasia	Normal	Normal	Impaired	Due to lesions of the arcuate fasciculus connecting Broca and Wernicke areas in the dominant hemisphere

[a]*Literal (phonemic) paraphasic error*: an error made by substituting a similar-sounding word for another (ie, "pat" substituted for "cat"). *Verbal (semantic) paraphasic error*: an error made by substituting words with similar meaning (ie, "cup" for "bottle").

[b]*Agrammatism* or *telegraphic speech*: Language content of spontaneously uttered sentences is condensed, missing many filler words, such as definite articles and sometimes verbs.

[c]Normal repetition in the setting of expressive, receptive, or global aphasia denotes transcortical expressive, transcortical receptive, and transcortical mixed aphasia subtypes.

additionally informative. Long-term memory can either represent a more prolonged delay in testing responses to the task of recollection or in some other tasks may instead represent long-term general or autobiographical knowledge. It is important to document the content asked to be remembered and the duration of time until asking for retrieval of information. Recall is entirely predicated on the patient's ability to register several items to be recalled, and this begins with preparing patient for this task in a minimally distracting environment.

In its simplest form in the neurologic examination, memory testing involves having a patient remember several items in the context of an examination to be recalled several minutes later. However, it largely serves to only test verbal memory of three unrelated words and does not take into account nondominant hippocampal function such as visuospatial memory or implicit memory associated with programmed motor tasks. Certainly, this is an important element of memory testing but is just one method of assessing memory among many.

Ideally, a test of three to five unrelated words, or a brief contextually related phrase (name and address of a fictional person), should be given to a patient to register and subsequently recall. It is most important for the examiner to use a series of words that have been rigorously studied to understand their cultural and socioeconomic norms; can be understandably and simply chosen from categorical clues, which may be given to help with recognition after-the-fact (eg, "the first word was a color"); can be recognizable from a list of similar words; and is also easily memorable to the examiner who may be giving such an examination many times over the course today.

Verbal memory can also be tested through repetition and recall of a simple story. This can be particularly effective in identifying the patient with a confabulatory amnestic syndrome (ie, Korsakoff syndrome) rather than anterograde amnesia (ie, Alzheimer disease). For example, a patient may be given a brief story to recall such as "Johnny had a red tricycle. Billy liked Johnny's red tricycle and stole it one day. Billy broke Johnny's red tricycle after he took it. When Johnny found out Billy had stolen the tricycle, he got very upset." A patient with a typical amnestic disorder may respond to this task by providing a few or a restricted set of elements germane to the story with the remainder unrecalled. In contrast, a patient with a confabulatory amnestic disorder may provide the initial basic elements of the story correctly but then provide an idiosyncratic thread far beyond the initial details provided in the story. Moreover, such a patient may begin with the same thread when testing the story on a follow-up examination, only to give a remarkably different yet linear story thereafter.

Nonverbal short-term memory is thought to be localizable to the nondominant hippocampus or most typically the right side in right-handed individuals. Formal neuropsychological testing often uses complex figure copying and recall testing, but testing visuospatial memory in the office can be challenging yet is possible. For instance, one can hide three objects within a room telling the examinee each time where each object is placed, to be registered and recounted several minutes later. A hospital corridor can be used as a visuospatial memory task by having a patient and examiner pass through a specific path, to be led by the patient immediately to demonstrate registration, and again several minutes later to demonstrate recollection.

Long-term memory likely engages separate circuits, widespread across the cerebrum, and is better categorized as public or autobiographical memory rather than a true function of working or recent memory. This memory type can also be easily conflated and is dependent on knowledge of worldly events and life experiences. Testing long-term memory can be approached by using a standardized set of questions, which should be well-known to the individual, such as sequential ordering of recent presidents. However, this can be easily tailored to a patient who may lack such conventional knowledge. For example, an aging sports enthusiast can be tested for knowledge of recent sports events important to him and hierarchically working back to biographical events, which must be corroborated by an informant. A test of recent worldly events likely more reflects function of the same recent memory circuits being tested by recollecting three unrelated words, given the need to both register and recall worldly information gathered through the news.

Calculation and Other Tasks of Attention and Concentration

Typical tasks of attention and concentration relate to the ability of a patient to attend and focus any specific, often narrow, set of tasks in real time. Bedside techniques in assessing concentration include serial subtraction, spelling a five-letter common word backward, or more simply involving stating the months of the year in reverse, days of the week in reverse, or counting from 20 down to 1. The examiner should begin with the most difficult task first. Elements of these examinations are often appropriately interpreted in the context of related domains such as executive function. For instance, the ability of a patient to count down from 20 may reflect the ability to attend to the task, whereas subtracting a series of changing answers may suggest intact or impaired executive or calculation abilities. Other more practical tasks may involve simple addition and subtraction, presuming appropriate levels of literacy and numeracy. Tasks such as making monetary change may give one not only a sense of the patient's calculation abilities but also any degree of functional impairment should a clear impairment emerge. For a patient residing in a major metropolitan area, the ability to appropriately make change at a hypothetical street-side food vendor can be such an example.

Assessment of attention and concentration also occurs in the course of other cognitive tests, including memory testing when several words are registered (intending to be later recalled), following a three-step command, or drawing a complex figure. As detailed earlier, it is not the performance on a single test that draws concern but rather an overall pattern that may emerge across the sequence of several tests.

Executive Function

Executive function can be demonstrated through several types of tasks highlighting the abilities or limitations of the frontal lobe or its principal subcortical circuits. Broadly speaking, these can be thought of as tasks, which demonstrate the ability of a patient to both maintain and shift between specific tasks or concepts, as demonstrated by examinations of either language or physical/motor abilities.

Common tests of executive function involve repetition of a number series in the reverse order in which it was given, complex tasks of addition or subtraction, or sequential tasks performed by the patient in a specific order and manner. Examples of executive tasks involving the hands may be in a standard set of hand movements such as knocking ("fist"), chopping ("edge"), and slapping ("palm") the hand on a table in sequence after being instructed to register the series, also known as the *Luria sequence*.

Tests of praxis may be considered to some degree to be tests of executive function, as a demonstration of ability or limitation in fine movement of the hands or limbs based on frontal lobe function.

It is also recognized that praxis requires not just motor planning and monitoring but also visuospatial and sensory input for refinement and placement and intact language function for understanding and executing the task. With this in mind, in contrast to weakness, praxis is the ability of a patient to coordinate and perform a simple or complex set of tasks based on instruction, independent of simple motor abilities. Simple, or ideomotor, tests of praxis involve single motions with contextually independent movements such as the ability of a patient to open and close a hand either to simple instruction or to demonstration. In contrast, ideational tests of praxis instead involve a complex task often with multiple steps of a well-known or overlearned task used in daily life. Examples include demonstration of brushing one's hair, brushing teeth, or blowing out a match. More specific examples for common daily tasks include putting on a coat, known as *dressing praxis*.

Visuospatial Function

Visuospatial function is often tested through tasks, which require ability to perceive, plan, orient, and synthesize visual images. As is the case for other cognitive tests, one might typically think of as specifically testing one domain, visuospatial abilities inevitably may have a basis in other domains including frontal executive function, specifically with planning, but are also reliant on memory (how one may be familiar with the stimulus object such as a clock or cube) or language (understanding the contextual basis for an image). The simplest of drawing tasks may limit the influence of frontal executive function on the ability of a patient to draw but must be taken in consideration relative to other nonvisuospatial tasks in order to fully interpret visuospatial test findings. Examples of visuospatial tasks include drawing intersecting pentagons, a circle with a tangentially touching square, or cubes, among other figures. More complex figures used in common practice, such as a clock drawing, can be very helpful in demonstrating visuospatial function but can also reflect a number of cognitive problems including planning, memory, as well as visual field deficits and can make interpretation challenging. As is the case with language, visuospatial function may be significantly impacted by educational history, in particular simple literacy. Individuals who may not have held a writing implement rarely in their life may have difficulty with relatively simple drawing tasks.

Higher Order Cognition

Higher order cognitive functions can reflect executive functions but represent a separate set of cognitive abilities, which are more often predicated on experiential knowledge and social norms. Tests of higher order function include interpretation of proverbs or common sayings and judgment as demonstrated by patient's response to simple hypothetical situations.

Ideally, one should select a few proverbs for such tasks, which are culturally sensitive, relatively ubiquitously known, and interpretable by both the patients and the examiner in the response. Using a relatively narrow set of appropriate phrases will also give the examiner better experience in anticipating a typical response from patients. Example phrases used in proverb interpretation include "two heads are better than one," "people in glass houses should not throw stones," and "don't count your chickens before they hatch." Examples of hypothetical situations to be provided for testing judgment may include asking for patient's response to discovering an unmailed fully addressed letter, or steps taken when facing a simple public emergency. As with any test, these must be interpreted with consideration of education and culturally based normative responses.

Key Psychiatric Examination Elements

The key elements of a conventional psychiatric examination will also be germane to many patients with neurologic disease, particularly those with an acquired cognitive disorder. The patient's reported symptoms of mood are recorded as mood, whereas the examiner's interpretation of the patient's mood is better characterized as affect. These can both be matched or unmatched in the context of examination and both are important distinctions to make for later interpretation.

Thought process is an important component of the psychiatric examination and is often discovered either during or in retrospect when the examiner reflects on a simple or challenging interview. Thought processes can be characterized using the following descriptors, which also have graphical corollaries to better conceptualize how conversation transpires (Fig. 4.2). These thought processes are linear, tangential, thought insertions, thought blocking, circumstantial (too many details, meandering but with spontaneous return), circumlocutions (talking around the subject with

FIGURE 4.2 Graphical representations of thought processes. Starting points are indicated with a *green dot* and final points with a *red dot*. *Lines* represent direction of conversation. (Adapted with permission from Edward R. Norris, MD [written communication, October 4, 2014].)

eventual arrival), and circumferential (talking around the subject without arrival). Thought content is considered the components and characteristics, which make up thought processes and include psychotic and nonpsychotic phenomenology. Important psychotic phenomenology either identified during examination or history includes delusions (fixed false beliefs), hallucinations (idiosyncratic, spontaneously perceived visual, auditory, sensory, olfactory, or gustatory stimuli), or illusions (misperceived complex visual or auditory perceptions based on real environmental cues). Other types of abnormal thought content include ideas of reference, sense of presence, or other thought idiosyncrasies.

Cranial Nerve Examination

The cranial nerve examination is an essential component of the neurologic examination that requires skilled training and expertise to interpret appropriately. However, when approaching the examination methodically, based on its principal components, rapid interpretation of the individual and localizing findings can be accomplished.

As is the case with the remainder of the general medical and neurologic examinations, the cranial nerve examination should be described in such a manner that only the elements of examination that were performed are those recorded. For instance, one may not assess olfaction in every neurologic examination, and it is unnecessary to state when it was not done. The examiner should demonstrate the findings again in a top-down approach beginning with findings identified in an ordinal manner, presenting the cranial nerves from lowest to highest number (begin with cranial nerve I and end with cranial nerve XII). Cranial nerve function should be described in the context of the test performed rather than the nerves themselves (eg, "eye movements fully intact" rather than "cranial nerves III, IV, and VI intact").

Cranial Nerve I (Olfactory Nerve)

Assessment of olfaction is important in certain neurologic diseases including frontal lobe tumor, head trauma, and degenerative disease, among others. Testing is composed of commonly recognizable smells, which are not caustic, toxic, or excessively potent in strength. Examples of commonly used, recognizable, and available smells include coffee, vanilla, and mint. These can be stored within a neurologist's equipment bag using plastic film canisters (although these are increasingly more difficult to find) or opaque contact lenses cases (so that the patient may not see the item to be smelled in advance). To test for smell, with the patient's eyes closed, have a patient fully close one of his or her nares and ask to take a deep breath with the item to be smelled placed immediately below the nares. Formal assessments of smell including distinction of various smells and smell thresholds are available, including on scratch-off cards, but at present are principally used in research applications.

Cranial Nerve II (Optic Nerve)

Assessment of cranial nerve II includes tests of visual acuity, visual fields, funduscopy, and pupillary light reaction.

Visual Acuity

Most standard physician examination kits include a Snellen card for testing visual acuity. One of the most important steps prior to performing a visual acuity examination is to know the exact distance at which the vision is to be tested. This is typically printed on the card and varies from 16 inches (or 40cm) for near vision to 6 ft (or 2m) for far vision (as a surrogate for a standard 20-ft (or 6m) distance examination). Begin by instructing the patient to put the hypothenar eminence of his or her hand against the bridge of the nose such that the eyes completely obstructed by the palm of the hand. If the patient is simply instructed to cover his or her eye with hand, there is a tendency of using the fingers to cover the eye and therefore the possibility of peeking through these fingers in order to improve or embellish the examination findings. Related to this issue, the examiner should always hold a visual acuity card to avoid a patient's temptation to bring the card closer to the face and conflate the exam.

Visual Fields

This examination should begin with the examiner standing at an arm's distance from the patient. Testing visual fields at a farther distance may only test central vision rather than demonstrate any frank field deficits as is desired by this test. Using the instructions previously described for covering the eye, the examiner should close their ipsilateral eye when facing the patient (the examiner should close his or her own left eye while examining the patient's left eye). With arms held aloft, the examiner should attempt to assess monocular visual fields at the left and right of meridian as well as above and below the equator of each tested eye. Generally speaking, the bedside visual examination test should be used to discover quadrantanopsias, binocular visual field loss, or homonymous hemianopsias. Any smaller field deficits would be far more difficult to identify on bedside examination and may require formalized visual field testing as is done in an ophthalmologist office (Fig. 4.3).

Methods of testing visual field include counting fingers within each of these quadrants, identifying a statically held hand with a wiggling finger, or moving a hand into the field being tested. Despite their routine inclusion on examination, most bedside techniques are poorly sensitive but highly specific to identifying visual field deficits.

Funduscopy (via Direct Ophthalmoscopy)

Funduscopy is marvelously distinguished as being the only part of the neuraxis which can be directly visualized. It provides a window into many diseases, including evidence of chronic systemic disease and acute neurologic emergency. However, the funduscopic exam can be neglected out of examiner discomfort or disinterest. The quality of the remainder of the examination and

FIGURE 4.3 Visual fields. (From Bickley L. *Bates' Guide to Physical Examination and History Taking*. 11th ed. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2013.)

FIGURE 4.4 Funduscopic view (right eye). (From Bickley L. *Bates' Guide to Physical Examination and History Taking*. 11th ed. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2013.)

history as performed by a referring physician, in the eyes of a consulting neurologist, may be predicated on inclusion or at least attempt of this aspect of the examination for this reason, particularly when called for by the diagnosis. Two main barriers may persist and limit the interest of a physician on performing this exam: perceived difficulty of use of the equipment and simple availability. Two forms of direct ophthalmoscopes exist for the bedside exam: conventional and panoptic. The conventional heads have the benefit of bright light for magnification, portability, and relatively ubiquitous presence of these heads in many clinics but are limited by perceived difficulty of use perhaps related to partial views of the optic disc even in optimal patients. The conventional heads are available in a normal size, as well as a smaller "micro" version, which offers even greater portability but faces the same limitations. The panoptic head offers the benefit of a wide field of view but is limited by expense and lower light intensity (which may limit visibility in patients with dense cataracts).

The essential aspects to be identified in funduscopy include characteristics of the optic nerve head including the cup, margins, and vessels as well as the immediately visualizable and relevant retinal components including the macula/fovea (Fig. 4.4). Visualizing the retina beyond the width of 2 or 3 optic disc diameters of most patients is particularly difficult by direct ophthalmoscopy.

Care should be taken to describe the color and shape of the disc as well as the cup-to-disc ratio if perceptible. A relative description of vessels can include the quantity and quality including relative diameter, or a suggestion of hypertensive change often described as "copper wiring," or "Arteriovenous (AV) nicking" when the vein appears compressed by a superimposed arteriole. Description of retinopathic changes including color variegations, vascularity, and plaques should be described. Having such an approach will leave more emergent and obvious abnormalities to the end of the focused examination and description.

Pupillary Light Response

Although listed here for the sake of organization with cranial nerve II, it is recognized that the pupillary light reflex involves both cranial nerve II and the pupillomotor circuit and fibers of cranial nerve III, which are further influenced by pupillary autonomic innervation. Two components of the pupillary response should be considered within each patient. These include the response of the ipsilateral and contralateral eyes to both direct and consensual light responses. While asking a patient to fixate on the examiner's face or another suitable target several feet away, using a light of sufficiently bright intensity, a narrowly focused beam is shown into a single eye with the examiner assessing for the ipsilateral and contralateral responses.

The swinging flashlight (Fig. 4.5) is another component of this test in which the initially examined eye is provided direct light followed by a rapid movement of light to be shown into the

FIGURE 4.5 Swinging flashlight test. (From Bickley L. *Bates' Guide to Physical Examination and History Taking*. 11th ed. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2013.)

FIGURE 4.6 Extraocular movements. (From Bickley L. *Bates' Guide to Physical Examination and History Taking*. 11th ed. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2013.)

contralateral eye followed by a movement back to the initially tested eye. The object of this examination is to identify either a lack of direct response (in the case of severe optic neuropathy) or paradoxical dilation during direct response (in less apparent cases, termed the *relative afferent pupillary defect*) as the swinging flashlight is shone back into an eye affected by an optic neuropathy.

In addition, pupillary asymmetries should be described and assessed in both a lit and a darkened environment with the use of tangential light (to assess pupillary size with minimal afferent stimulus, as may be relevant in diagnosing a Horner syndrome).

Extraocular Movements (Cranial Nerves III [Oculomotor Nerve], IV [Trochlear Nerve], and VI [Abducens Nerve])

The elements of testing extraocular movements include demonstration of limitations of excursion of either individual or consensual gaze, rapidity of saccades, preservation of smooth pursuits, and the control of multiple types of extraocular movements, both large and small excursions as well as slow and fast movements.

Prior to any testing of eye movements, the patient should be carefully examined for any spontaneous eye movements when focusing on a fixed near target placed several feet before the patient. Although this technique may demonstrate spontaneous eye movement abnormalities including so-called square wave jerks, finer perception of such movements may be identified during funduscopic examination, which magnifies subtle spontaneous eye movements otherwise missed during casual visual inspection.

To test for restriction of gaze, the patient (Fig. 4.6) should be asked to follow the finger or a similar near target at approximately an arm's length distance from the patient moving through a typical H pattern followed by assessment of near point convergence and pupillary accommodation. Care should be taken not to move through these movements too quickly; otherwise, saccadization of pursuits may occur and potentially mislead the development of the oculomotor examination.

To test for rapidity of saccadic eye movements at a similarly near distance, the patient should be asked to fixate on the examiner's nose while both hands are placed in mid position between the patient and examiner at about a shoulder width apart. With one hand wiggling (to indicate a target) and the patient staring at the examiner, the patient is instructed to look at the wiggling stimulus, followed by instructions to return to gaze back to the nose. After a series of repeated assessments, the rapidity of saccadizations as well as the ability to accurately fixate on the lateral and midline targets can be assessed using this technique. An alternating bright and dark cloth tape to stimulate optokinetic nystagmus can be an additionally helpful tool in potentially identifying lateralized saccadic eye movement deficit.

To further test for the accuracy of fixation and the ability to maintain fine, fixed, and accurate extraocular movements, the patient can be asked to additionally follow a moving target through an unpredictable series of movements in either the horizontal or vertical plane. A consistent need to provide a corrective saccade in all, or a single direction, provides a localizable deficit.

Cranial Nerve V (Trigeminal Nerve)

Principally, the trigeminal nerve serves to provide facial sensations including touch, temperature, and pinprick of the face and anterior elements of the mouth. Vibratory sensations applied to the face likely reflect neck vibratory sensory function, which is seldom if ever absent on examination and thus cannot be discerned from facial sensation. Joint position sense may only be evident in the jaw and rarely if ever demonstrably found.

As is the case for sensory testing within the torso and limbs, the goal of the sensory examination is to identify the modality of sensory deficit and thus the potential tracts and nerve fiber types involved against the pattern of sensory deficits identified on examination (Fig. 4.7). Patterns include laterality and segmentation in the face. Palpating the face (as well as within the mouth) can be useful in trying to identify trigger points in patients with suspected trigeminal neuralgia.

FIGURE 4.7 Dermatomes of the face and head. *(1)*, *(2)*, and *(3)* correspond to divisions of the trigeminal nerve. (From Bickley L. *Bates' Guide to Physical Examination and History Taking*. 11th ed. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2013.)

The fifth nerve also controls the muscles of mastication including the masseter and temporalis. Demonstrating weakness of these muscles may be identified through gross testing of the jaw opening and closure but rarely identified on examination outside of severe muscular weakness. Palpation of a tender temporomandibular joint or identifying crepitus may be useful in assessing a patient with headaches; this may be done by palpating the joint while the patient opens and closes the jaw.

Cranial Nerve VII (Facial Nerve)

The goal of testing the seventh nerve is to identify specific patterns of weakness, which may be evident at rest, volitional action, or through unintentional means such as laughter. Start with simple inspection of the face, including critical appraisal during the interview. Flattened nasolabial folds will be extinguished by forced movements but may reveal low tone as a presenting sign in acute ischemic stroke or even Bell palsy. Thereafter, turn to specific movements to demonstrate either segmental or unilateral weakness of the face. Specific facial movements that should be tested include brow raising, forced eye closure including assessment of "burying the eyelashes," smiling, pursing the lips, and puffing the cheeks, to determine an upper versus lower motor neuron abnormality and thereafter which branches of the lower cranial motor nerve may be involved. Although patients may be able to demonstrate these functions on their own, assessment of force can be made by the examiner by pulling on any of the muscles being tested one side against the other.

Testing for unilateral loss of taste perception may be helpful in assessing the localization of a Bell palsy. To test for taste, take a commonly perceived recognizable flavor, such as salt or sugar, which are also conveniently typically on hand in most physician office practices or hospital-based settings. Place a small amount of this into a small cup with water and stir with a cotton-tipped applicator. With the patient's eyes closed and tongue protruded, attempt to paint the salty or sweet solution on the side of suspected facial paresis (affected and presumed ageusic side). The patient should be instructed not to draw his or her tongue into the mouth until asked whether or not he or she can taste the applied mixture. Upon demonstration or confirmation that no taste is perceived, the patient is then allowed to draw the tongue into the mouth and swirl around the fluid, and presumably, the taste will be perceived by the normal, contralateral side of the tongue.

FIGURE 4.8 Weber hearing testing for lateralization of hearing. (From Bickley L. *Bates' Guide to Physical Examination and History Taking*. 11th ed. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2013.)

Cranial Nerve VIII (Vestibulocochlear Nerve)

The bedside examination of the cranial nerve VIII typically focuses on hearing but may include additional testing for the patient complaining of dizziness. Testing for hearing includes relatively crude screening measures to be done at the bedside beginning with perceptions of hearing grossly as simply assessed through the interview by the examiner's vocal volume required. Additional tests include using the 512 Hz (or similarly high tone) tuning fork for the Weber test for lateralized hearing loss (Fig. 4.8) and the Rinne test to identify the typical perception of air conduction being longer than bone conduction of sound (Fig. 4.9).

Additional crude hearing tests include whispering a number into the patient's ear to be then repeated by the patient, or audible hand movements including lightly rubbing the fingertips,

A

B

FIGURE 4.9 Rinne hearing testing for air > bone conduction. **A:** Bone conduction; once sound extinguishes. **B:** Air conduction is tested. (From Bickley L. *Bates' Guide to Physical Examination and History Taking*. 11th ed. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2013.)

escalating to flicking the fingernail, and then snapping. Clearly, such testing cannot supplant more formal audiography. For the severely hearing impaired, history development and examination may be aided by placing the stethoscope earbuds into the patient's ears, with the examiner speaking into the diaphragm.

Vestibular testing in the dizzy patient should focus on attempting to identify central versus peripheral localizations of vertigo. Specific tests to apply to any such patient include the Dix-Hallpike maneuver and the head impulse nystagmus test (discussed later in this chapter and additionally in Chapter 5). An additional test, the Fukuda marching test, performed by having a patient march in place with eyes closed, can demonstrate a rotating station and evidence of a hypofunctioning vestibular apparatus on the side to which the patient turns. These tests in combination can help localization in disorders of dizziness and vertigo.

The Lower Cranial Nerves Involved in Speech (IX [Glossopharyngeal Nerve], X [Vagus Nerve], and XII [Hypoglossal Nerve])

Speech, or the articulation of language, can be very helpful in localizing a neurologic disorder. Table 4.3 reviews phonemes of speech and typical neurologic localization. The patient should be asked to speak each of these phonemes with particular attention paid to whether a singular or grossly abnormal speech pattern is evident.

Additional testing includes asking the patient to open his or her mouth to assess symmetry in raising the palate (Fig. 4.10), assessment of phonation for vagal nerve abnormalities, and protrusion of the tongue in one direction or another to suggest hypoglossal dysfunction.

Of note, a patient with a seventh nerve paresis may give the false impression of having an ipsilateral hypoglossal dysfunction simply because of the formation of the shape of the mouth. Thus, in patients with facial nerve weakness having tongue protrusion tested, the examiner should begin by forcibly opening the mouth in a symmetric fashion such that the tongue is allowed to exit the mouth in an unobstructed manner.

Cranial Nerve XI (Accessory Nerve)

The spinal accessory nerve has two principal functions including shoulder shrug by the trapezius muscle and head turning by the sternocleidomastoid muscles. Forcibly testing each of these movements may be of lower yield than simply observing shoulder shrug, which may demonstrate either low tone or slow or clumsy movement in a patient presenting with hemiparesis. Although frequently tested and included in neurologic examinations, head turning and shoulder shrug may only rarely be focally affected and thus infrequently provides additional information to the examination above and beyond the history and other findings on examination.

TABLE 4.3 Phonemes Tested for Patterns of Dysarthria

Phoneme	Neurologic Localization
Labial sounds: "ma," "pa"	CN VII
Pharyngeal/guttural sounds: "ga" and "ka"	CN IX, X
Lingual sounds: "la," "ta"	CN XII
Bland dysarthria (all sounds similarly involved)	Corticobulbar tracts to subcortical
Additional Speech Patterns	
Scanning or "metronomic" speech	Cerebellar
Dysphonic (hoarse) voice	CN X

Abbreviation: CN, cranial nerve.

FIGURE 4.10 Examination of palate/uvula elevation to command. Weakness on the right leads to a deviation of the uvula to the left (unaffected side). (From Bickley L. *Bates' Guide to Physical Examination and History Taking*. 11th ed. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2013.)

Motor Examination

The motor examination has several principal components, including inspection, palpation, tone, power, and drift testing and other tests for identifying subtle lateralized motor deficit.

Inspection is an essential element of the neurologic examination particularly for a patient being assessed for the first time. Relatively straightforward diagnoses are often missed by failing to place the patient into a gown. Inspection may identify focal or global patterns of atrophy, fasciculations, or rashes, which may be germane to muscular disorders. In determining the presence of fasciculations, it is often necessary to use a tangential light or observe subtle movements in the muscles affecting the overlying hair. Palpation of the muscles is indicated in a patient presenting with weakness or chronic pain, seeking to identify trigger points, but may be additionally helpful in other conditions, such as chronic low back pain in discerning musculoskeletal from neurogenic pain.

Observation and careful assessment of involuntary movements is also part of the motor examination. Tremor and involuntary movements may be identified on casual inspection or more formally during strength, tone, and coordination testing. Primary features of tremor include its relative frequency (fast vs slow), context in which it appears (with action [including specific actions if relevant], rest, posture, or multiple contexts), the consistency with which it appears during the examination (how frequently it is present), the severity of the tremor (ranging from mild to disabling), and the quality of the tremor itself (ranging from sinusoidal and monotonous to irregular and chaotic or myoclonic). Other more chaotic or less predictable movement disorders include ballism (rapid, wild, and chaotic movements), chorea (chaotic or unpredictable movements, which may give the appearance of fidgeting), athetosis (slow "snakelike" movements),

and myoclonus (rapid, brief jerks). Dystonia presents with activation of agonist and antagonist muscles and tends to present in fixed or slowly varying/moving positions, which may also be accompanied by tremor. In each involuntary movement, careful observation of regions of the body or limbs affected, intensity of movements, how often they are present during the encounter, and whether or not they are functionally debilitating, should be determined. A more in-depth description and assessment of various movement disorders is provided in Chapter 13.

Of all the components of the neurologic examination, muscle tone testing is one that requires particular attention to nuance and is learned principally through practice when working alongside a skilled examiner. Tone of the neck, arms, and legs should be assessed in all patients. Tone testing begins by the examiner moving a limb through several planes of motion simultaneously to prevent the patient from either contributing or diminishing tone in a volitional manner. Tone may be normal, increased, or decreased and may vary according to position and speed of limb movements. *Rigidity* refers to tone which is static or constantly present and to a similar degree throughout range of motion of a joint or limb. *Spasticity* refers to tone which is not constant and instead is velocity dependent; spasticity is notable for a sudden release of tension when a limb is moved quickly and/or at extremes of joint flexion/extension. In contrast, *paratonia* refers to tone which is also velocity dependent but predictably increases with increased speed of movement and decreases at lower speeds. Paratonia may also be referred to as *gegenhalten* ("holding against"). Tone may be decreased in peripheral neurologic and cerebellar disorders, as well as in acute stroke. To facilitate tone (or draw out subtle features), the patient should be instructed to perform distracting tasks, such as contralateral movements, or even a complex arithmetic question, simply to further diminish the influence of volitional control of tone.

Motor strength examination, or power testing, is among other essential elements of the motor examination. In each patient, power testing must be considered in the context of other principal motor components. The score to evaluate all motor examination findings (0-5) has been modified over time and may be idiosyncratically applied by differing examiners. The scale often leaves the neurologist to adjust findings using subtleties in the scale such as +/− symbols rather than just relying on numbers as the scale suggests. The definitions of each strength value are listed in **Table 4.4**.

TABLE 4.4 Medical Research Council Strength Assessment Scale

Strength Rating	Description
5	Full power to confrontational testing by the examiner (normal)
4	The examiner is able to overcome the strength of the patient but near full strength remains.
3	Sufficient strength to overcome gravity only
2	Flexion possible when out of the plane of gravity
1	Demonstration of muscle contraction but without any demonstrable joint movement
0	No appreciable movement

It is important to test a single muscle side to side rather than testing an entire side of the patient followed by a comparison of the strength in entire opposite side. A direct comparison of each muscle or joint side to side allows for a far more instructive examination and allows subtle asymmetries to be revealed. Correct positioning of the patient and examiner is also important to accurately interpret strength. Whenever possible, the examiner's body position should mimic the patient. Muscles being tested for strength should always be at mid position (**Fig. 4.11**) because at extremes of the joint position may convey inaccurate perception of superb strength or frank weakness. Other references are suggested as an additional guideline for testing each muscle group in a comprehensive manner, which is beyond the scope of this review.

Drift testing is an essential component of the motor examination because of its ability to detect subtle hemiparesis. *Pronator drift testing* is accomplished by having a patient either sitting or lying in bed, with hands outstretched before the patient, palms

FIGURE 4.11 Testing strength. The example of biceps brachialis strength testing is provided to demonstrate the importance of (1) isolation of the muscle being tested, (2) testing force at mid position, and (3) the examiner's own arm similarly positioned to the patient. (From Bickley L. *Bates' Guide to Physical Examination and History Taking*. 11th ed. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2013.)

facing upward. With eyes closed for approximately 10 seconds, the patient's hand position should remain static. Ordinarily, a patient should be able to maintain this forced anatomic position, rather than a relaxed or natural pronated position. During testing for pronation, an altitudinal drift may be apparent such that the hand does not pronate but moves in either an upward or downward or even a variable vertical direction. Drift testing in the foot involves bringing the leg off the bed and an approximate 30° angle and with the patient's eyes closed, maintaining that position for approximately 10 seconds. Any drift including a drop of the leg back onto the bed suggests a positive finding. Other tests that can be used to detect or confirm the presence of a subtle lateralized motor deficit include the arm roll test (in which the unaffected arm tends to "orbit" the affected, less mobile arm) and various finger tapping techniques (with velocity, dexterity, and amplitude of the finger or toe taps reduced on the affected side).

Additional components of the strength examination may also include an assessment of fatigability as may be seen with myasthenia gravis or facilitation as may be seen with the Lambert-Eaton myasthenic syndrome. Fatigability may be assessed by having a patient hold up his or her arms aloft for approximately 30 seconds and assess for fatigability when myasthenia is suspected. In contrast, facilitation may be elicited by having a patient's strength tested before and after sustained contraction (eg, sustained biceps contraction).

Coordination

The coordination examination is used to principally identify abnormalities grossly associated with ataxia and cerebellar dysfunction. Cerebellar examination techniques include assessments of appendicular and axial functions. Appendicular coordination may be demonstrated by asking the patient to extend a pointed index finger to a target provided as far away from the patient as possible, followed by touching a near target such as the nose or chin (preferable for an obviously ataxic patient given the risk for eye injury). More challenging tasks include a finger chase task, in which the patient's index finger follows as closely as possible to an examiner's brief movements with varying speed and distance. These tasks may draw out subtle corrective movements and overshooting the target. Axial coordination may be assessed using a heel-to-shin test, in which the patient places the heel of one foot against the shin of the opposite leg, with it moved vertically several times. Tests of coordination additionally include rapid movements such as finger taps (or more finely demonstrated as an index finger tapping on the thumb interphalangeal joint), rapid alternating movements (flipping the hand over, opening/closing the hand), and heel/toe tapping. These tasks are also essential in patients with suspected movement disorders. Additional coordination testing is comprised within the gait examination listed in the following section.

Gait, Station, and Body Movements

Observation of a patient's gait and station may not only be the first and importantly impressionistic examination done in the course of a visit as the patient enters from the waiting room but also the last done as part of a formal examination. Assessing primary station, or stance, is assessed without instruction and involves assessment of width of the feet and posture while spontaneously standing. Asking the patient to narrow the station, by placing the feet together, is the first step in assessing for imbalance and axial ataxia. The Romberg test is performed by having the patient stand feet together, arms outstretched, followed by eye closure once the examiner is able to determine no postural sway, which could be due to other causes such as cerebellar disease. Once eyes are closed, a tendency to sway or fall is indicative of either a defect in vestibular or proprioceptive function. Additionally, ability to maintain balance in blinded tandem station, forward and reverse tandem gait, and on a single foot have become part of standardized office-based postconcussion assessments. However, without baseline assessments, understanding normal findings for some of these and other tests of balance can prove difficult, especially in aging populations.

The gait assessment begins with watching casual gait, assessing for stride length and speed, and lateralizing findings such as a shoulder droop, asymmetric arm swing, or leg circumduction, followed by tandem gait. Specific patterns in gait may be revealed, including steppage gait (excessively flexing the hips to overcome foot drop), or a "waddling" gait (suggesting proximal leg weakness) is further described in Chapter 15. Special attention should also be given to ability to stand, quality of turns (en bloc or with appropriate, distinct steps), and passage through thresholds (doorways). The pull test, which evaluates postural stability, is performed by having the examiner stand behind the patient pulling suddenly backward on the shoulders. In a normal response, the patient makes a quick corrective step to maintain balance. An abnormal response is characteristic of parkinsonism and other diseases that affect postural stability. Toe walking assesses gastrocnemius strength as much as it does test balance, although this may be distinguished when the examiner offers a steadying hand.

Deep Tendon and Other Reflexes

As is the case for motor examination, several essential elements allow for accurate interpretation of the deep tendon reflexes. These include correct positioning of the patient and assessing reflexes for subtle asymmetry. Most neurologists have a favorite type of hammer, one that is ideally of sufficient mass to allow for a low-velocity strike to consistently test the deep tendon reflex, as opposed to a low-mass hammer requiring a high-velocity strike, and which may be more likely to injure the examiner or patient than elicit the actual response intended.

As is the case for muscle testing, other resources are suggested to identify the optimal locations in which to strike the tendon of each respective deep tendon reflex, but several principal ones are provided in Table 4.5.

Reflex testing should include biceps brachialis, brachioradialis, triceps, patellar, crossed adduction in the legs, and ankle jerks on all newly assessed patients, and recorded using a standard scale (Table 4.6). Finger flexion, thumb flexion (Hoffman reflex), and plantar scratch response ("Babinski sign" when positive) should be routinely assessed. Additional tests of the tendon reflex including jaw, shoulder, abdominal scratch, and deep abdominal reflexes may be relevant and pursued in the appropriate context.

Direct Muscle Percussion

Direct muscle percussion elicits a contraction response, which is thought to characterize the shortening of fascicles. It is most easily seen when directly striking the opponens pollicis, eliciting thumb flexion, but can be identified visually in other large muscle bodies including the biceps and gastrocnemius. The muscle

TABLE 4.5 Deep Tendon and Other Motor Reflexes[a]

Deep Tendon Reflexes

percussion reflex may help localize lower motor neuron disorders and will be abnormal in tetany (increased) and myotonic conditions (increased and/or sustained response with slow relaxation phase). In upper motor neuron disorders, both the deep tendon and muscle percussion reflexes are increased. In primary myopathies, both are decreased. In lower motor neuron disorders, deep tendon reflexes will be decreased, whereas muscle percussion reflexes will often elicit a contraction. Muscle percussion contraction responses may be decreased in severe, chronic neuropathic disorders with neurogenic atrophy (eg, Charcot-Marie-Tooth, and may be preserved or unchanged in myositis.

Frontal release signs, including snout (induced by tapping over the philtrum), glabellar (Myerson sign, blinking induced by tapping over the glabella and out of the patient's view), and palmomental signs (mentalis muscle movement induced by scratching the thenar eminence of the palmar surface), are commonly included in neurologic examinations but are of questionable sensitivity and specificity. Other frontal release signs include a snout and suck responses (when the inner lips or nasolabial fold are touched or stroked) as well as a grasp response (typically referring to the hand, grasping with objects or hands briefly placed in the palm, can be seen in the toes and mouth). These are not true reflexes but are instead thought to represent loss of normal cortical circuitry, which ordinarily inhibits these "primitive" adaptive responses and can be seen in a host of neurologic disorders including stroke, trauma, and degenerative disease.

Sensory Examination

Similar to guidance provided in trigeminal nerve assessment, the approach of these sensory examination is intended to identify the nerve fiber type and tract involved, as based on the tested modality. Identifying patterns of deficit are a principal goal of

TABLE 4.6 Deep Tendon Reflex Assessment Scale

4	Pathologic; with sustained clonus elicited and typically light percussion to elicit brisk reflexes
3	Usually pathologic; several beats of clonus or spread to adjacent ipsilateral muscle group or same group tested contralaterally are evident
2	Normal reflex; may have a brisk upstroke but without pathologic features
1	Hyporeflexic; contraction of the muscle as expected but insufficient force to move the joint
0	Hyporeflexic; no movement of the muscle or joint

sensory examination, including laterality, dermatomal distribution (both radicular and peripheral dermatomal patterns), possible spinal level, and determination of a distal or proximal pattern of abnormality (Fig. 4.12). Each domain should be assessed with these in mind.

Essential components of the sensory examination include assessment of light touch (using a cotton-tipped applicator or fine gauze), pinprick (using disposable implement such as a safety pin or a broken wood handle of a cotton-tipped applicator), temperature (actually heat conduction of a metal damper on a low-frequency tuning fork), vibratory sensation, and joint position sense.

One of the great challenges of the sensory examination is determining objective measures within a largely subjective examination. Of all of the modalities included, only joint position sense is truly objective nature. Patients either do not perceive (totally anesthetic), occasionally misperceive (partially anesthetic patient), or exactly misperceive (somatoform presentation) the stimulus.

Light touch, pinprick, and temperature sensations are all assessed in a relatively similar manner by asking the patient to indicate perception or intensity of the intended stimulus. An appropriate reference point may be to provide the stimulus to the cheek (for light touch, temperature, and pinprick sensation) or finger (for vibration), followed by the area being tested and

FIGURE 4.12 Dermatome maps. (From Bickley L. *Bates' Guide to Physical Examination and History Taking*. 11th ed. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2013.)

FIGURE 4.13 Vibration sensation testing. (From Bickley L. *Bates' Guide to Physical Examination and History Taking*. 11th ed. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2013.)

FIGURE 4.14 Joint position sense testing. (From Bickley L. *Bates' Guide to Physical Examination and History Taking*. 11th ed. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2013.)

asking the patient to assess whether they are equivalent. Although percentages of difference may be appropriate to determine the nature deficit, other familiar analogies may be more understandable, such as considerations of money ($1.00 versus 10 ¢ in lieu of percentages).

Vibration sense is crudely assessed by using a 128-Hz tuning fork struck and then with its base applied to the distal most bony prominence available on a patient's limb, such as the interphalangeal joint of the great toe or the tip of the finger (**Fig. 4.13**). The patient is then asked to assess the presence and persistence of the vibratory stimulus until it is no longer perceived, at which time it may then be applied to the more proximal limb, such as moving from the toes to the finger and asking if the stimulus is still perceived. Two control conditions are established—one within the patient as well as the examiner presuming vibratory sensory function is normal in the examiner.

Joint position sense is performed by having the examiner touch the lateral aspects of the distal interphalangeal joint and asking the patient to close his or her eyes (**Fig. 4.14**). Using the smallest excursion possible, the patient is asked to perceive the movement (either upward or downward direction). The examiner should be careful to record the responses in a patient incorrectly identifying the position change, as consistently wrong answers may suggest a feigned response. As is the case with vibratory sensory testing, assessment of the patient's sensation should begin with the most distal position and then moved proximally.

Higher order cognitive sensory testing should be included in patients with suspected cognitive impairment but can only be fully interpreted when performed in limbs/hand unaffected by primary sensory loss. These tests are myriad but commonly include assessment of graphesthesia (by drawing a number or letter on a patient's palm while eyes are closed; several training trials may be required), stereognosis (placing a single or similar objects within the palm of the patient such as paperclip/key or various familiar coins), and assessment of perception of simultaneously applied bilateral stimuli (by touching both hands after assessment of primary sensory function).

Additional Neurologic Tests for Special Conditions

Dix-Hallpike Maneuver

The Dix-Hallpike maneuver can be useful in a patient with suspected benign paroxysmal positional vertigo (BPPV; or a similar vertiginous syndrome) who is actively or very recently affected. It is often positive in patients with posterior semicircular canal BPPV, which is the semicircular canal implicated in the majority of BPPV presentations. Patients in a quiescent period will most likely be asymptomatic and have no demonstrable signs on examination. As demonstrated in the Figure 4.15, the patient begins

FIGURE 4.15 Dix-Hallpike maneuver. *1* and *2* correspond to the first and second positions of the maneuver. (From Fife TD, Iverson DJ, Lempert T, et al. Practice parameter: therapies for benign paroxysmal positional vertigo [an evidence-based review]: report of the Quality Standards Subcommittee of the American Academy of Neurology. *Neurology*. 2008;70[22]:2067-2074.)

FIGURE 4.16 Head impulse test. **A-C:** With the patient fixated on a distant target, the examiner rapidly turns the head from 15° to the right to 15° to the left, with normally maintained fixation demonstrated. Testing in the opposite direction, **D-F** illustrate a right peripheral vestibular lesion with a severe loss of right lateral semicircular canal function and no vestibulo-ocular reflex as demonstrated by loss of fixation **(E)** followed by a voluntary corrective saccade **(F)**. (From Halmagyi GM, Cremer PD. Assessment and treatment of dizziness. *J Neurol Neurosurg Psychiatry*. 2000;68[2]:129-134.)

seated with the head turned about 45 degrees in a single direction. The patient is then positioned supine with the head slightly extended (either hanging off the examination table or supported by the examiner's arm beneath the shoulder). With the patient's eyes open, looking at the examiner's face, the expected positive test will reveal a 5- to 10-second delay in onset of rotatory nystagmus and recapitulation of symptoms. These should resolve after 10 to 30 seconds. A brief vertical nystagmus phase may occur upon sitting. In most cases, the finding should be unilateral and serves as the first step of the Epley maneuver (see Chapter 5).

The Head Impulse Test

A relatively new bedside diagnostic test may be better at identifying some brainstem strokes than diffusion-weighted imaging. One component of the head impulse–nystagmus test of skew is the head impulse test. The test can only be applied and appropriately interpreted in a patient acutely symptomatic with vertigo or a suspected related disorder (ie, cerebellar dysfunction). As demonstrated in the Figure 4.16, the examiner rotates the patient's head about 30° off mid position. With the patient's gaze fixated on the examiner's face, the head is rapidly rotated to mid position. If a catch-up saccade is repeatedly identified, particularly unilaterally, a peripheral vestibular etiology is suggested but must be interpreted in the context of other neurologic examination findings because ischemic vestibular mimics do occur.

Phalen and Tinel Signs

When considering the diagnosis of carpal tunnel syndrome, in addition to inspection of the hand and assessment of weakness of the opponens pollicis, two additional tests can be helpful. The Tinel sign (Fig. 4.17A) involves percussing the course of the median nerve across the wrist, whereas the Phalen sign (Fig. 4.17B) involves keeping a sustained position of flexed wrists. Both the Phalen and Tinel signs seek to recapitulate the patient's specific neurologic syndrome and not simply discomfort.

FIGURE 4.17 **A: Tinel sign.** (From Bickley L. *Bates' Guide to Physical Examination and History Taking*. 11th ed. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2013.) **B: Phalen sign.** (Courtesy of James M. Noble, MD.)

FIGURE 4.18 Straight leg raise test. (From Bickley L. *Bates' Guide to Physical Examination and History Taking*. 11th ed. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2013.)

A Tinel sign can also be identified anywhere a suspected focal neural compression may have occurred, such as across the olecranon or the fibular head.

Straight Leg Raise

The straight leg raise test is used in the context of diagnosing sciatica. As demonstrated in the Figure 4.18 with the patient lying down, the heel of the ipsilateral (affected) leg is raised straight off the bed by the examiner to about 30° to 45°; at its conclusion, the toe may be passively dorsiflexed.

A contralateral (crossed) straight leg raise test may be applied to the opposite leg, only if the affected leg has a positive finding; the contralateral test seeks to recapitulate the affected leg symptoms, still on the affected side. To be considered a positive sign, the patient should report the specific pain (typically lancinating) syndrome, which led to the patient to seek attention. The ipsilateral test is highly sensitive but weakly specific, whereas the contralateral test is highly specific but weakly sensitive.

Additional Spinal Reflexes (Male Patients Only)

The Cremasteric Reflex

The cremasteric reflex tests for the L1-L2 reflex arc and may be considered as a localizing test finding when considering a patient with a lower spinal cord neurologic disorder or as confirmatory reflex examination in patients exhibiting evidence of reflex abnormalities in ipsilateral limb muscle groups. The response will be absent in both central and peripheral neurologic disorders. It is performed by lightly stroking a slightly noxious tactile stimulus proximally along the inner aspect of the thigh (suggest a disposable item such as tongue depressor or hard end of a wooden swab stick). The testicle will normally rise ipsilaterally in conjunction with the applied scratch.

Bulbocavernosus Reflex

The bulbocavernosus should be applied specifically to individuals suspected of experiencing acute spinal cord injury. The test involves two potential stimuli: (1) squeezing on the glans penis or clitoris or (2) gently tugging on a Foley catheter while monitoring for anal sphincter contraction; this can be done electrophysiologically or manually. The response will be lost in acute spinal shock.

As is the case with any potentially sensitive element of physical examination, but particularly with these tests, given their involvement of examination of genitalia, inclusion of an examination chaperone, particularly one of the same gender as the patient, should be included in all such examinations.

Anal sphincter Tone

A digital examination of anal sphincter tone is an important component of a complete neurologic examination, particularly in a patient presenting with a spinal cord syndrome. Using a single-gloved, lubricated finger, and with adequate patient preparation and instruction, insert the finger to the anus such that spontaneous tone can be determined. If low tone is identified, instruct the volitionally squeeze the anus on the finger.

Tests of Malingering

Myriad tests have been proposed to potentially identify patients with embellished, feigned, or malingered signs. Of those, which have been studied to identify their sensitivity and specificity, most are imperfect. However, as detailed earlier, when findings are identified in the context of others on the neurologic examination, some of these additional tests can be useful in the appropriate context. Whenever considering applying these tests, it is most important to do so tactfully because both the act of applying and interpreting the findings takes a very skilled and advanced examiner to both appropriately perform and inform the patient of the findings with appropriate sensitivity and respect for the patient. Although some may consider these examination components potentially deceitful of the patient, they can be highly instructive, potentially avoid substantial evaluative cost and even morbidity (particularly when they may obviate invasive, unnecessary, or misleading diagnostic measures), and when appropriately disclosed, potentially highly therapeutic. The following are several techniques that can be particularly useful on examination.

Hoover Sign

This test is used to identify feigned unilateral leg weakness. Following assessment of the normal leg, with the patient lying down supine, the examiner places a hand beneath the heel of the normal leg and asks the patient to raise the opposite (presumed weak) leg. Normally, a patient attempting to raise the affected leg should depress the normal leg toward the examination surface, with the force felt by the examiner. Caution in its interpretation should be raised in the patient with evidence of dyspraxia, delayed responses, or possible paraparesis/quadriparesis.

Head Vibratory Hemianesthesia

Patients with psychogenic examinations may have hemianesthesia affecting the entire body including the face, often to all modalities tested. Vibratory sensation in the head is likely, principally or at least partially, perceived by transmitted signal to the neck and to a lesser extent the head. Several methods to identify feigned from true facial hemianesthesia using vibratory sensation have been proposed. One approach involves, with the patient's eyes open, placing a 128-Hz tuning fork centrally above the brow, visible to the patient. While keeping the base position of the fork static, tilt the fork toward the affected (anesthetic) side followed by a tilt to the normal side. Record the patient's responses. Repeat the measure, out of sequence, with the eyes closed to discern an examination discrepancy.

FIGURE 4.19 Bowlus and Currier test. Sequence of the Bowlus and Currier test, followed **A, B, C,** then **D.** Pinprick sensory testing is performed using a normal approach, comparing the left and right hand at baseline. When a nonphysiologic sensory examination is suspected, instruct the patient to position the hands in to that shown in **D.** Sensory testing is repeated quickly to identify discrepancies in examination. (Photos by James M. Noble, MD.)

Body Hemianesthesia

The Bowlus and Currier test (**Fig. 4.19**) can be a useful approach in distinguishing the patient with psychogenic hemianesthesia. As shown in the figures, the patient begins by pointing the thumbs down with the arms outstretched. Then, the right wrist is crossed over the left, and fingers are then interdigitated and flexed. Keeping the fingers locked together, the elbows are flexed, and the forearms supinated such that the hands are nearly at the patient's chin, thumbs pointing upward. Quickly thereafter, the examiner tests pinprick sensation on the knuckles of either hand, seeking not only for consistency but also for the rapidity with which the patient provides the answer. Substantial hesitation or inconsistency with primary sensory examination supports a feigned neurologic examination.

Dizziness, Vertigo, and Hearing Loss 5

J. Kirk Roberts

KEY POINTS

1. It is often more useful for diagnosing the cause of dizziness and vertigo to rely on associated characteristics such as triggers, duration, history of prior episodes, and associated symptoms than focusing on subjective features of the dizziness.
2. In a first attack of acute vertigo, the major diagnostic consideration is differentiating stroke from vestibular neuritis. Helpful factors include a history of vascular risk factors, HINTS testing (evaluation of head impulse test, nystagmus, and skew), and other neurologic symptoms or signs.
3. Posterior canal benign positional vertigo can be diagnosed in those with positional vertigo and a characteristic nystagmus on positioning and is often effectively treated with repositioning maneuvers.

INTRODUCTION

Dizziness is an imprecise term used to describe a variety of symptoms including but not limited to vertigo, light-headedness, faintness, giddiness, disequilibrium, confusion, etc. It affects nearly one-quarter of the general population and is a common complaint in the emergency room and in the office of the neurologist, otolaryngologist, and internist. The causes of dizziness are varied, span across medical subspecialties, and range from the relatively benign to life threatening. The evaluation of dizziness is made more difficult by the fact that the symptom is difficult for the patient to describe. A first step is an attempt to categorize dizziness into vertigo, presyncope, disequilibrium, and other or nonspecific dizziness as noted in Table 5.1.

Vertigo is an illusion of motion, either the environment or the self, most commonly rotatory but may be translational or tilting. *Presyncope* is the sensation encountered before loss of consciousness and is discussed in Chapter 6. *Dysequilibrium* is not a sensation of motion but a feeling of imbalance or unsteadiness and is discussed in Chapter 15. Other or nonspecific dizziness include those whose symptoms do not easily fit into one of the aforementioned categories or fall into more than one category. Rather than using the qualitative description of dizziness to categorize the subtype, it is often more helpful to use characteristics such as onset, duration, triggers, history of prior episodes, and associated symptoms in evaluating these patients.

VERTIGO

Neuroanatomy

Vertigo primarily results from disorders of the vestibular system, which includes the vestibular labyrinth, vestibular nerve, vestibular nuclei in the brainstem, vestibular portions of the cerebellum, connections between these structures, and only rarely higher in the cerebrum. The vestibular labyrinth, located in the temporal bones, is composed of the three orthogonally oriented semicircular canals (anterior, posterior, and lateral) and the vestibule, which contains the otolith organs, the utricle and saccule, which are also angled at approximately 90° to each other. The former responds to angular acceleration and the latter to linear acceleration including translation or tilt. When the head is rotated, endolymphatic fluid in the semicircular canals lags behind,

TABLE 5.1 Dizziness Subtypes

	Vertigo	Presyncope	Disequilibrium	Nonspecific Dizziness
Symptom description	Illusion of motion, imbalance	Going to pass out, faint	Imbalance, unsteady, symptoms not in the head	Light-headed, foggy, floating
Onset	Usually sudden	Usually sudden	Sudden to slow	Poorly defined
Duration	Seconds to hours	Seconds to minutes	Acute to chronic	Subacute to chronic
Triggers	Head motion, position change	Orthostatic maneuvers, urination, cough, dehydration	Standing or walking, not when sitting or lying	Stress, situational, nonspecific
History	None or episodes	None or episodes	Chronic	Chronic
Associated symptoms	Nausea, ear symptoms (hearing loss, tinnitus), brainstem symptoms (diplopia, slurring, numbness, weakness, incoordination, ataxia)	Graying vision, warmth, diaphoresis, nausea, palpitations, chest pain	Slurring, incoordination	Many

TABLE 5.2 Peripheral Versus Central Vertigo

	Peripheral	Central
Nausea/vomiting	Severe	Mild/moderate
Imbalance	Mild/moderate	Severe
Ear symptoms (hearing loss, tinnitus, pain)	Common	Rare
Other neurologic symptoms	Rare	Common

leading to a deflection of the gelatinous cupula within the canal, which activates or inhibits the firing of hair cells. Activation on one side is paired with inhibition in the complementary canal on the other. The otolith organs, the utricle and saccule, contain hair cells on which calcium carbonate crystals, the otoconia, rest. Translational motion or tilt (via gravity) will activate or inhibit these cells. From the vestibular labyrinth, neurons travel centrally through the vestibular portion of the eighth cranial nerve into the brainstem to the vestibular nuclei and then project on to the cerebellum, ocular motor nuclei, spinal cord, and, via some less well-understood pathways, to the cerebrum. Integration of the combinations of activations and inhibitions of the various components of the vestibular system of both ears, along with visual input and proprioceptive input, detects motion, rotation, translation, and tilt and affects eye movements and posture.

Vertigo can result from disorders of the peripheral vestibular system (labyrinth or nerve) or central vestibular system (brainstem, cerebellum, connections, and rarely, cerebrum), and this localization is the natural next step in the evaluation of vertigo. Table 5.2 lists some differentiating features.

Diagnosis

In the patient with the acute first presentation of vertigo, the most significant concern is evaluating for stroke (ischemic or hemorrhagic) and differentiating from vestibular neuritis. A history of vascular risk factors and other neurologic symptoms, headache, and complaints related to the brainstem is particularly important. However, the lack of those symptoms does not exclude an ischemic etiology. Patients presenting with isolated vertigo have a threefold increased risk of stroke compared to the general population that increases with the presence of multiple vascular risk factors. In the patient presenting with recurrent attacks of vertigo, the major differential includes benign positional paroxysmal vertigo (BPPV), Ménière syndrome, and migraines. Vertebral artery compression from neck rotation is a very rare case of episodic dizziness or vertigo.

Focused History

Loss of vestibular function affects eye movements and image stabilization, balance, and spatial orientation. In addition to vertigo, patients may feel tilted, the world jiggling while walking (oscillopsia), spatially disoriented, imbalanced, and, rarely, suffer from drop attacks, where they may feel pulled or pushed to the ground. These drop attacks, known as *Tumarkin crises*, are most commonly seen in Ménière syndrome but also may occur in other vestibular conditions.

Focused Examination

The examination of the patient with vertigo includes all components of the neurologic examination with special attention to

TABLE 5.3 Peripheral Versus Central Nystagmus

	Peripheral	Central
Appearance	Combined torsional, horizontal, and vertical Nystagmus beats away from the affected side.	Often pure vertical, horizontal, or torsional; any trajectory
Fixation	Inhibits	No effect
Gaze	Obeys Alexander law (Nystagmus increases when looking toward the side of the fast phase.)	May change direction; does not obey Alexander law

certain aspects. The ear must be examined and hearing must be tested. Examination of the eyes is particularly important. Start by observing for nystagmus in primary gaze and with eye movements in all directions. Reobserve after removing the ability to fixate by the use of Frenzel lenses, goggles with magnifying lenses that allow you to see eye movements but does not allow the patient to fixate. If Frenzel lenses are unavailable, fixation can be eliminated during ophthalmoscopic examination of one eye by covering the eye not being examined with your free hand and observing for nystagmus of the optic disc. Remember that this movement is in the opposite direction of the movement of the front of the eye. Pay attention to the type of motion (horizontal, vertical, torsional, mixed), the effect of fixation, and the effect of gaze. Pendular nystagmus is sinusoidal, whereas jerk nystagmus, the more commonly observed nystagmus, is composed of slow drift in one direction and a rapid correction back. It is caused by an imbalance in vestibular input, either peripheral or central. Characteristics of peripheral versus central jerk nystagmus are listed in Table 5.3. Jerk nystagmus is named for the direction of the fast phase and can be further categorized by its trajectory and the conditions under which it is seen. Some particular forms of nystagmus and their relevance are listed in Table 5.4.

In addition to nystagmus, unilateral peripheral vestibular dysfunction leads to a subtle skew deviation of vertical eye position with the ipsilateral eye lower in the orbit relative to the contralateral eye and conjugate torsion of the eyes to the ipsilateral side. In addition to the ocular motor findings, the patient usually has a small head roll or tilt to the affected side and a tendency to fall toward the same side. They may perceive vertical to be slightly tilted. Testing for past pointing will reveal deviation to the ipsilateral side. Tandem gait and Romberg test will be impaired but are not specific. The Fukuda step test, marching in place with the eyes closed, will show deviation toward the side of the vestibular lesion.

Head Impulse Test

The head thrust or head impulse test evaluates for loss of vestibular input from either the vestibular labyrinth or vestibular nerve to the vestibulo-ocular reflex. It is performed (Fig. 5.1) by asking the patient to focus on a target in front of him or her. The head is then rapidly rotated a small amount (approximately 15°). In normal circumstances, the eyes remain focused on the target. A vestibular lesion on the side to which the patient is being rotated will lead to a loss of fixation and the eyes will turn with the head and require a saccade to refixate. The input from the horizontal canal is most commonly tested by rotating the head in the horizontal plane. The other canals may also be tested by rotating the head

TABLE 5.4 Subtypes of Nystagmus

Jerk Nystagmus
Gaze-evoked: nystagmus at the extremes of gaze beating in the direction of gaze
Physiologic: fine nystagmus; usually fatigues **Drug/medication:** often seen with sedatives and anticonvulsants **Brainstem/cerebellar lesions:** may be sustained **Rebound nystagmus:** After looking eccentrically for approximately 1 min on return to primary gaze, there is nystagmus beating in the other direction associated with brainstem or cerebellar lesions. **Bruns nystagmus:** Slow, large-amplitude nystagmus in one direction and rapid, small-amplitude nystagmus in the other direction suggest a cerebellopontine angle lesion on the side of the slow, large-amplitude nystagmus.
Horizontal Nystagmus
Peripheral nystagmus: Nystagmus only beats in one direction, away from the affected side, obeys Alexander law, usually mixed with torsion, and inhibited by fixation. **Central nystagmus:** Nystagmus may change directions, may be purely horizontal, does not obey Alexander law, and not inhibited by fixation. **Periodic alternating nystagmus:** nystagmus alternating directions every 1-2 min associated with lesions at the cervicomedullary junction or in the cerebellum **Dissociated nystagmus:** nystagmus differing between the eyes seen with internuclear ophthalmoplegia or mimicked by myasthenia gravis
Downbeat nystagmus: Nystagmus usually increases on down and lateral gaze seen with involvement of the dorsal medulla or the cerebellar flocculus or projections associated with lesions at the cervicomedullary junction, medications (lithium, carbamazepine, phenytoin), alcohol, hypomagnesemia, thiamine deficiency, paraneoplastic syndromes, cerebellar degenerations, and other.
Upbeat nystagmus: associated with brainstem and cerebellar lesions, most commonly the medulla
Congenital nystagmus: often a mixture of jerk and pendular nystagmus
Convergence-retraction nystagmus: part of Parinaud dorsal midbrain syndrome; convergence and retraction of the eyes
Positional nystagmus: seen with specific head motions and is discussed more in the following text
Pendular Nystagmus
Acquired: seen with brainstem and cerebellar lesions
Congenital: often a mixture of jerk and pendular nystagmus
Spasmus nutans: infant onset; nystagmus is asymmetric and rapid, often associated with head nodding and head turning; usually resolves
Associated with visual loss
Seesaw nystagmus: opposite conjugate vertical and torsional movements associated with mesencephalic or parasellar lesions
Oculopalatal myoclonus: rhythmic 2-3-Hz movements seen late after lesion of Mollaret triangle
Oculomasticatory myorhythmia: rhythmic movements of eye convergence and contraction of masticatory or other muscles seen in 20% of patients with Whipple disease

along the plane of the canal in question. The head impulse test is generally normal in those with central causes of vertigo. In patients presenting with an acute vestibular syndrome, the use of the head impulse test along with the evaluation of nystagmus and the presence of skew (HINTS testing) can be used to distinguish an acute peripheral vestibular lesion from an acute central lesion such as cerebral infarct with more accuracy than magnetic resonance imaging (MRI). Dynamic visual acuity also evaluates this reflex. It is performed by testing vision while stationary and then while shaking the head at approximately 2 Hz. Most can read no more than two to four lines worse on the eye chart with normal function of at least one labyrinth.

FIGURE 5.1 The head thrust test. (Modified from Barraclough K, Bronstein A. Vertigo. *BMJ*. 2009;339:b3493.)

Dix-Hallpike Maneuver

Positional maneuvers must also be performed to look for BPPV, and this is discussed in more detail in Chapter 60. In this condition, vertigo is precipitated by characteristic head motions due to otolith debris loose in the semicircular canals, most commonly the posterior canal. To evaluate, the Dix-Hallpike maneuver (see **Fig. 4.15**) is performed by having the patient sit with the head turned 45° to one side. The patient is then laid back into a supine position with the head extended 30° and is observed for nystagmus for at least 30 seconds. A positive test will result in symptoms of vertigo after a few seconds, lasting up to a minute, and the observer will see upbeating and rotatory nystagmus of the upper pole of the eye toward the ground. This response will fatigue with repeated maneuvers.

Less common horizontal canal BPPV might be revealed with horizontal nystagmus on Dix-Hallpike and is more reliably investigated with lateral head and body turns while supine. Anterior canal BPPV is quite rare. If the nystagmus is not characteristic for BPPV in terms of type, latency, and fatigability nystagmus, then a central lesion must be considered. BPPV is best treated with repositioning maneuvers designed to "roll" the otolith debris out of the affected canal.

Various causes along with characteristics of some of the causes of vertigo are listed in Tables 5.5 (peripheral) and 5.6 (central). More details may be found in other chapters.

TABLE 5.5 Causes of Peripheral Vertigo

Cause	Characteristics
BPPV	Brief, recurrent, positional nystagmus only in provoking position
Vestibular neuritis	Acute, single episode, viral prodrome
Ramsay Hunt syndrome (herpes zoster oticus)	Acute, single episode, vesicles in/near the ear, facial nerve palsy, deafness
Ménière syndrome	Recurrent, last minutes to hours, unilateral ear symptoms of fullness, hearing loss, tinnitus
Trauma	History of trauma
Perilymphatic fistula	Episodic, associated with Valsalva, loud sounds (Tullio phenomenon), history of trauma
Superior canal dehiscence	Episodic, associated with Valsalva, loud sounds
Cogan syndrome	Ménière-like syndrome with interstitial keratitis
Acoustic neuroma	Rare vertigo, more imbalance, unilateral hearing loss or tinnitus
Medications	Aminoglycoside exposure
Otitis	Evidence of otitis
Labyrinth ischemia	Presence of vascular risk factors, sudden vertigo, and hearing loss
Recurrent vestibulopathy	Recurrent attacks but without the ear symptoms to suggest Ménière syndrome

Abbreviation: BPPV, benign positional paroxysmal vertigo.

Diagnostic Testing

Diagnostic testing that is most useful in patients with vertigo includes comprehensive auditory examination to determine ear involvement especially with any complaints of hearing loss or tinnitus. Imaging is indicated when a central cause is under consideration and in other select cases. Computed tomography (CT) does not image the posterior fossa well and MRI is the imaging modality of choice. In the evaluation of superior canal dehiscence, CT better images the bony dehiscence that is the cause, although newer MRI techniques are being developed. Videonystagmography or electronystagmography is helpful if BPPV is considered, but nystagmus is not evident on clinical exam or if a unilateral vestibular lesion is suspected but not confirmed on clinical exam (see also Chapter 29). Rotational chair testing is also helpful in this circumstance and if bilateral vestibular dysfunction is suspected.

TABLE 5.6 Causes of Central Vertigo

Cause	Characteristics
Migraine-associated vertigo	Migraine history
Cerebral ischemia/hemorrhage	Vascular risk factors, other neurologic symptoms and signs, more prominent dysmetria or ataxia
Multiple sclerosis	History or presence of other neurologic symptoms or signs
Tumor	Presence of other neurologic symptoms or signs
Craniocervical junction abnormalities (Arnold-Chiari, basilar impression, etc)	Associated with headaches, neck pain, other lower cranial nerve involvement
Episodic ataxia type 2	Episodic vertigo and ataxia lasting hours to days
Cerebellar or spinocerebellar degenerations	More commonly ataxia and not vertigo
Mal de débarquement	After boat travel (or other), sensation of motion persists.

Treatment

The treatment of vertigo is primarily directed at the causes and is discussed in the appropriate chapters. Nonspecific treatments for attacks of vertigo, some off-label, include antihistamines, anticholinergics, benzodiazepines, and antiemetics for nausea and vomiting, and are listed in **Table 5.7**. Symptomatic medications should be stopped after severe symptoms remit. Vestibular rehabilitation is thought to benefit by promoting compensation, facilitating strategic substitution, limiting inactivity, and in the case of BPPV, repositioning otolith debris. There are some concerns that medications may interfere with rehabilitation.

TINNITUS

Tinnitus is the perception of sound in the head when there is no external sound present. Disability may range from none to severe. Subjective tinnitus is heard only by the patient, whereas objective tinnitus is also heard by the examiner. Tinnitus can be classified into pulsatile and nonpulsatile tinnitus, with pulsatile tinnitus usually indicating a vascular etiology. **Table 5.8** lists various causes of tinnitus.

Neuroanatomy

Most tinnitus is related to sensorineural hearing loss at the cochlear or cochlear nerve level and the tinnitus is thought to be generated in the central nervous system. Less commonly, tinnitus originates from structures in proximity to the ear, most commonly vascular structures.

Diagnosis

One should inquire about the quality of the sound, whether it is episodic or constant, whether it is pulsatile or nonpulsatile, and precipitating and alleviating factors. Pay particular attention to a history of ear disease or trauma, hearing loss, noise exposure, headaches, and conditions that predispose to atherosclerosis such as hypertension, hypercholesterolemia, diabetes mellitus, and smoking. Tinnitus that is pulsatile or humming and changes with exercise or head motion raises more concern for a vascular etiology.

Examination and Diagnostic Testing

The ear and surrounding structures must be inspected; hearing must be tested; and one should listen for bruits in the neck, over the skull, and over the eye. If a vascular etiology is suspected, further evaluation might include duplex Doppler, MRI without and with contrast, magnetic resonance angiography, CT angiography, and, in some cases, conventional angiography.

TABLE 5.7 Medications Used in the Treatment of Vertigo

	Medications	Adverse Effects
Antihistamines		
Meclizine	12.5-25 mg up to every 6 h as needed for vertigo	Drowsiness, blurred vision
Diphenhydramine	25-50 mg up to every 6 h as needed for vertigo	Drowsiness, confusion, restlessness, tachycardia, blurred vision, dryness of mucous membranes, thickened bronchial secretions, difficulty urinating, constipation
Dimenhydrinate	50-100 mg up to every 6 h as needed for vertigo or motion sickness	Drowsiness, restlessness, tachycardia, blurred vision, thickened bronchial secretions
Anticholinergics		
Scopolamine	One 1.5-mg transdermal patch every 72 h as needed for vertigo or motion sickness	Drowsiness, dizziness, confusion, agitation, blurred vision
Benzodiazepines		
Diazepam	1-5 mg up to every 8 h as needed for vertigo	Drowsiness, confusion, amnesia, tolerance, withdrawal
Lorazepam	1-2 mg up to every 8 h as needed for vertigo	Drowsiness, confusion, amnesia, tolerance, withdrawal
Alprazolam	0.25-0.5 mg up to every 6 h as needed for vertigo	Drowsiness, confusion, amnesia, tolerance, withdrawal
Clonazepam	0.25-0.5 mg up to every 8 h as needed for vertigo	Drowsiness, confusion, amnesia, tolerance, withdrawal
Antiemetics		
Prochlorperazine	5-10 mg orally up to every 6 h as needed; 25 mg rectally up to every 12 h as needed; for vertigo with nausea/vomiting	Hypotension, extrapyramidal symptoms
Metoclopramide	5-10 mg up to every 6 h as needed for vertigo with nausea/vomiting; do not use continuously for >12 wk.	Extrapyramidal symptoms including tardive dyskinesia
Ondansetron	4-mg up to every 8 h as needed for vertigo with nausea/vomiting	Constipation, dizziness, malaise, QT prolongation

Treatment

The treatment of tinnitus from vascular abnormalities or from other nonaudiologic abnormalities are usually treated by treating the underlying condition. Patients with tinnitus thought to be related to disorders of the auditory systems should be referred for complete audiologic evaluation (CAE) and otolaryngology consultation. Unfortunately, the success of treatment of this type of tinnitus is marginal. Hearing aids may benefit patients with presbycusis. Behavioral therapies may help. The success of masking devices producing low-level sounds and electrical stimulation are unproven. Medication trials have largely been disappointing.

TABLE 5.8 Causes of Tinnitus

Pulsatile Tinnitus
Arteriovenous malformations/arteriovenous fistulas
Vascular stenosis/turbulence
Paragangliomas
Increased intracranial pressure
Jugular dehiscence
Tensor tympani or stapedius muscle spasm or myoclonus
Palatal spasm or myoclonus
Eustachian tube dysfunction
Nonpulsatile Tinnitus
Sensorineural hearing loss (age, toxicity, noise exposure, etc)
Otosclerosis
Middle or inner ear trauma
Acoustic neuroma/cerebellopontine angle lesions
Temporomandibular joint dysfunction
Craniocervical junction and cervical spine disorders
Medications

HEARING LOSS

Hearing loss is common. It is typically categorized as conductive, usually from a problem in the outer or middle ear, sensorineural, usually from a problem in the inner ear or the along the eighth cranial nerve, or mixed. It can be unilateral or bilateral.

Diagnosis

The history should focus on the degree of hearing loss, time course, laterality, types of sounds affected, and precipitating factors, along with associated features such as tinnitus, vertigo, other cranial nerve abnormalities, headache, or other neurologic symptoms. Family history is important especially in those with onset at a younger age.

Outer and middle ear problems causing conductive hearing loss are listed in Table 5.9, whereas inner ear and problems along the eighth cranial nerve causing sensorineural hearing loss are listed in Table 4.10. Central nervous system causes of hearing loss are rare.

Sudden Hearing Loss

The patient with sudden sensorineural hearing loss, usually unilateral, over 1 to 3 days is a particular subcategory of hearing loss. The incidence is 5 to 27 per 100,000 people per year and is most common in the middle aged. The etiology in most cases is never identified. Autoimmune, inflammatory, infectious, and ischemic

TABLE 5.9 Causes of Conductive Hearing Loss
Outer Ear
Congenital

Infection
Eustachian tube dysfunction
Tympanic membrane perforation
Otosclerosis
Trauma
Tumors (cholesteatoma, paraganglioma)

etiologies are postulated. Many report tinnitus, and some report vertigo. Urgent evaluation is warranted. A repeated history suggests Ménière or a chronic autoimmune condition. Neck pain might suggest vertebral artery dissection. The internal auditory artery is a branch of the anterior inferior cerebellar artery. Updated clinical practice guidelines are available. CAE should be performed. MRI or auditory brainstem response looking for retrocochlear pathology should be performed. Routine laboratory testing should not be performed unless clinically indicated. The use of oral glucocorticoids within 2 weeks of onset is an option and many do treat. Treatment with hyperbaric oxygen combined with steroid therapy is also an option for early treatment or for salvage therapy for those who have not responded. Salvage therapy with intratympanic steroids is recommended within 2 to 6 weeks following onset for those who have incomplete recovery. Antivirals are not routinely recommended. Prognosis is related to the severity of hearing loss at onset.

Examination

Examination must include visual inspection of the ear along with tests of hearing. Patients should be able to hear a finger rub or a whisper a few inches away from the ear. The Weber and Rinne tests provide additional information. The Weber test is performed by placing a 256-Hz tuning fork in the center of the forehead equidistant from both ears. A normal response is hearing the tuning fork similarly in both ears. A patient with a conductive hearing loss will hear the tuning fork louder in the affected ear, and a patient with sensorineural hearing loss will hear the tuning fork louder in the unaffected ear. The Rinne test is performed by placing a 512-Hz tuning fork on the mastoid bone behind the ear and asking when the sound is no longer heard. It is then moved to 1 to 2 inches from the external auditory canal. In a patient with normal hearing or sensorineural hearing loss, the sound will still be heard, as air conduction is better than bone conduction. In a patient with conductive hearing loss, bone conduction is better than air conduction. Further hearing testing includes a CAE with pure tone audiometry, speech reception thresholds and discrimination, impedance testing, and acoustic reflexes. Imaging with MRI and/or CT will depend on the clinical situation.

TABLE 5.10 Causes of Sensorineural Hearing Loss	
Congenital	Autoimmune/inflammatory
Presbycusis	Ischemic
Infection	Metabolic
Ménière syndrome	Ototoxic
Noise exposure	Structural
Trauma	

Treatment

The treatment of hearing loss is directed at the cause along with hearing amplification and cochlear implantation. The first step involves identifying appropriate candidates based on discussions about the patients' hearing difficulties and desires, the audiogram, and what hearing aids can offer. Many of those with significant hearing loss do not wear hearing aids for a variety of reasons including the financial cost, cosmetic issues, not understanding the degree of hearing loss, etc. Candidates for cochlear implants have moderate to severe hearing loss for whom hearing aids are not working well. Patients do not need to be totally deaf to be considered for cochlear implants.

Syncope 6

Tina T. Shih

KEY POINTS

1. Syncope is a transient loss of consciousness due to decreased cerebral blood flow.
2. Syncope is rapid in onset and short in duration with spontaneous, complete, and rapid recovery.
3. Distinguishing syncope from seizure requires the clinician to take a meticulous history of the event.

INTRODUCTION

Sudden alteration of consciousness is a common presenting symptom in a variety of clinical contexts, from the emergency room to the outpatient clinic. The vast majority of events can be categorized as either seizure or syncope or the proverbial "fit" versus "faint." This chapter aims to provide a practical framework to help the clinician distinguish between these two diagnoses. Syncope is defined as a transient loss of consciousness due to decreased cerebral blood flow. Seizure is defined as a transient alteration in brain function due to abnormal electrical cerebral activity. When evaluating any patient with a history of transient loss of consciousness, clinicians should take a very careful history of the event itself. The clinician would be best served spending the majority of the encounter interviewing the patient and eyewitnesses, eliciting the symptoms and signs in a step-by-step fashion in order to understand the order and tempo of the events as they unfolded. Skipping this step often results in misdiagnosis and wasted health care dollars spent on inconclusive or even misleading test results.

EPIDEMIOLOGY

Syncope is a common symptom, experienced by about half of the world's population at some point in their lifetime. Most individuals do not seek medical care. Syncope accounts for approximately 1% to 2% of emergency room visits. Vasovagal syncope is far and away the most common cause of syncope in young people and the most common cause of syncope in all age groups. Syncope due to cardiac reasons is the second most common cause. The incidence of syncope appears to increase significantly with age, doubling in individuals older than the age of 70 years as compared to younger cohorts. The causes of syncope in older populations are varied and can include vasovagal, cardiac, and orthostatic etiologies. Orthostatic hypotension is very rare in patients younger than the age of 40 years.

PATHOBIOLOGY

Syncope is defined as a transient loss of consciousness due to insufficient blood flow to the brain, resulting in a loss of postural tone. The underlying basic mechanisms resulting in decreased cerebral blood flow are *reduced cardiac output* and/or *low peripheral vascular resistance* (blood pressure). A loss of consciousness in supine individuals occurs within 6 to 8 seconds after cardiac asystole, whereas in upright individuals, tilt table recordings demonstrate loss of consciousness if systolic blood pressure drops below 60 mm Hg.

Causes of Syncope

Figure 6.1 describes the relationship between the various causes of syncope and the basic physiologic mechanisms (low cardiac output and low peripheral vascular resistance) that mediate this phenomenon.

Neurally Mediated Reflex Syncope

The most common type of syncope, accounting for over half of cases, is reflex syncope, also known as *neurocardiogenic syncope*. In this form of syncope, an external factor or set of circumstances (apprehension of pain, cough, head turning, etc) leads to bradycardia, hypotension, or a mixture of both phenomena. Reflex syncope is divided into two main categories: vasovagal syncope and carotid sinus syncope (**Table 6.1**).

Vasovagal Syncope

Vasovagal syncope, the most common type of reflex syncope, is caused by a brief loss of neurally mediated circulatory control and is generally associated with a benign prognosis. Vasovagal syncope can be subdivided into three major categories: postural, central, and situational. In the postural form of vasovagal syncope, a common patient narrative might describe a young person attending a hot and crowded school assembly or concert, standing for a long period of time and having skipped a recent meal and ingested some alcohol. In cases of centrally mediated vasovagal syncope, the trigger may involve sudden pain (commonly in the setting of venipuncture), apprehension of pain, or emotional shock immediately preceding the fainting episode. Less commonly, syncope occurs in specific situations or appears to be temporally related to specific triggers. Older men may report symptoms soon after arising from bed and emptying a distended bladder. Some young people describe recurrent syncope after exercise. Others describe syncope after coughing, laughing, or sneezing. It is not unusual for a history of vasovagal syncope to run in families. Surprisingly, despite the prevalence of this condition, the underlying pathophysiology of vasovagal syncope remains a mystery. Physiologists have yet to identify why an emotional state or coughing or prolonged standing can lead to a sudden decrease in blood pressure or why vasovagal syncope can recur frequently in some individuals, rarely in others.

Carotid Sinus Syndrome

A more unusual type of reflex syncope is carotid sinus syndrome, which occurs when normal stimulation of an unusually sensitive carotid sinus leads to hypotension and/or bradycardia. This diagnosis should be suspected in older individuals who report unexplained falls or syncope with almost no prodromal symptoms; occasionally, a history of head turning, wearing a tight-collared shirt, or

FIGURE 6.1 Pathophysiologic basis of the classification. Abbreviations: ANF, autonomic nervous failure; ANS, autonomic nervous system; BP, blood pressure; OH, orthostatic hypotension; periph. resist., peripheral resistance. (Obtained from this article Moya A, Sutton R, Ammirati F, et al. Guidelines for the diagnosis and management of syncope [version 2009]. *Eur Heart J.* 2009;30[21]:2631-2371.)

TABLE 6.1 Causes of Syncope

Neurally Mediated Reflex Syncope
• Vasovagal syncope Central (emotional stimuli) Postural (prolonged upright position) • Situational (specific triggers) • Micturition, defecation, coughing, sneezing, laughing, weight lifting, post exercising, trumpet playing
• Carotid sinus syndrome
Cardiac Syncope (Cardiovascular)
• Arrhythmias
• Structural heart disease/mechanical
Syncope due to Orthostatic Hypotension
• Autonomic failure • Multiple system atrophy, diabetes, amyloidosis, hereditary polyneuropathy
• Drug induced • Antihypertensives, diuretics, antianginal, tricyclic antidepressants, levodopa, lithium, alcohol
• Hypovolemia • Anemia, failure to thrive, malnutrition
• Postural orthostatic hypotension syndrome

shaving preceding syncope is elicited, but in general, this diagnosis is often difficult to make and is considered after extensive diagnostic testing has been inconclusive or negative.

Cardiac Syncope

The most dangerous type of syncope is cardiac syncope, when a transient loss of consciousness is caused by either cardiac arrhythmia or structural heart disease. In a large population-based study of syncope, cardiac syncope was associated with a twofold increased risk of dying, regardless of etiology, as compared to individuals without a history of syncope.

Arrhythmias are the most common cause of cardiac syncope, and both tachyarrhythmias and bradyarrhythmias have been implicated. The most common arrhythmia associated with syncope is sinus node dysfunction. Other arrhythmias include atrioventricular conduction system disease, supraventricular tachyarrhythmias, and ventricular tachyarrhythmias.

Mechanical or structural causes of cardiac syncope include prior myocardial infarction, cardiomyopathy, aortic stenosis, mitral stenosis, pericardial tamponade, myxoma, aortic dissection, and pulmonary emboli.

Because of the high morbidity associated with cardiac syncope, it is imperative to consider this diagnosis when evaluating an individual with syncope. The clinical features most predictive of cardiac syncope include age older than 60 years, male gender, known

structural heart disease, fewer events (less than three events by history), syncope while supine, and syncope during effort/exercise.

Syncope Due to Orthostatic Hypotension

Unlike individuals with vasovagal syncope (who have an intact autonomic nervous system at baseline), individuals with syncope due to orthostatic hypotension are believed to have underlying autonomic dysfunction involving sympathetic efferent pathways, preventing appropriate vasoconstriction upon standing. Therefore, when an individual with this condition rises from a supine position, he or she experiences an abnormal drop in systolic blood pressure. Patients who present with this form of syncope are usually elderly, and this condition rarely occurs in individuals younger than 40 years of age. The clinical history may reveal other symptoms upon standing, which include light-headedness/dizziness or presyncope, weakness/fatigue/lethargy, diaphoresis, vision disturbances (graying of vision, enhanced brightness, tunnel vision), muffled hearing, and/or pain in the shoulders ("coat hanger" distribution), invariably associated with an upright position.

Causes of orthostatic hypotension include the following: hypovolemia from anemia or malnutrition; medications such as antihypertensives, diuretics and tricyclic antidepressants; autonomic failure from neurodegenerative disorders such as multiple system atrophy, hereditary, toxic or paraneoplastic peripheral neuropathies and secondary neuropathies due to systemic diseases such as diabetes and amyloidosis (see Table 6.1). A rare form of orthostatic hypotension with dizziness and near syncope is postural orthostatic hypotension syndrome, a poorly understood syndrome typically seen in young women with chronic fatigue syndrome. The syndrome consists of an increase in heart rate and unstable blood pressure upon standing.

DIAGNOSIS

Differentiating Syncope From Seizure

The key to making the correct diagnosis is obtaining a detailed narrative of the event from the patient and eyewitnesses. Although many patients and witnesses will use terms such as *passing out* or *fainting* to describe either condition, it is important to delve further and elicit a second-by-second account of the patient's actual experience. An inability to obtain such a narrative severely hampers making a diagnosis, which further diagnostic testing is unlikely to resolve. The clinical hallmarks of syncope are rapid onset, short duration, and complete rapid recovery.

The most important clinical features distinguishing syncope from seizures are the following: (1) precipitating stimuli or situations, (2) prodromal symptoms before losing awareness, and (3) the postevent recovery (Table 6.2).

TABLE 6.2 Clinical Features Distinguishing Syncope From Seizure

Feature	Syncope	Seizure
Before a Spell		
Trigger (change in position, prolonged standing, emotion, Valsalva, exercise)	Common	Rare
Sweating, light-headedness, graying of vision, and/or nausea	Common	Occasional
Occurring out of sleep	Rare	Occasional
Aura (déjà vu, olfactory hallucination, unilateral symptoms)	Rare	Common
During a Spell		
Pallor	Common	Rare
Cyanosis	Rare	Common (generalized tonic-clonic seizures)
Duration of loss of consciousness	<20 s	>60 s
Movements	A few rhythmic jerking movements of the limbs, lasting <15 s	Prolonged stiffening of the limbs (tonic), transitioning to rhythmic jerking of the limbs (clonic), lasting ~1-2 min
Automatic behavior (lip smacking, picking, patting)	Occasional	Common (focal dyscognitive seizures)
Tongue biting (lateral)	Rare	Occasional
Frothing/hypersalivation/vomiting	Rare	Common
After a Spell		
Confusion/disorientation	Rare, <30 s	Common, several minutes or longer
Diffuse muscle pain	Rare, brief	Common, hours to days
Creatinine kinase elevation	Rare	Common (especially after 12-24 h)
Focal neurologic signs	Rare	Occasional
Incontinence	Rare	Occasional
Headache	Rare	Common
Amnesia for the event	Less common (sometimes seen in elderly)	Common

Clinical Features of Syncope

Syncope typically occurs when patients are upright (standing or sitting) and can be triggered by exercise, coughing, bearing down (Valsalva maneuver), venipuncture, prolonged standing, or pain. Presyncope begins with a sense of unwellness accompanied by light-headedness and nausea. Patients may feel weak and unsteady on their feet, followed by a decreased awareness or detachment from their environment. Immediately before losing consciousness, patients experience a "graying of the vision" and/or "muffling" of ambient sounds. Eyewitnesses will often note that the patients appear pale or ashen, diaphoretic, and tachypneic. Sometimes, an attack can be aborted if the patients lie down quickly or lower the head below the level of the heart. Once patients lose consciousness, they will lose tone in the muscles of their trunk and legs and they will limply collapse to the floor. On the ground, the limbs are flaccid and patients continue to appear pale and sweaty. The period of unconsciousness is generally brief, lasting only seconds up to 1 to 2 minutes. If the degree of decreased cerebral perfusion is profound enough, patients may display a few jerking movements of the limbs ("convulsive syncope"), but this is also typically very brief (lasting only a few seconds). Generally, the pulse and blood pressure quickly return to normal with the patients in the recumbent position, and they rapidly regain consciousness and quickly become oriented and aware of their surroundings. Patients will often realize that they have fainted and remember details of the event up until the moment of losing consciousness. They might experience mild fatigue or brief disorientation after the event, but this should not last more than a few minutes.

Clinical Features of Seizures

Epileptic *seizures* are defined as transient alterations in brain function due to abnormal electrocerebral activity. The clinical manifestations of seizures vary widely, depending on brain volume involvement and neuroanatomic location of electrical activation. Seizures can occur day or night, regardless of whether the patient is awake or asleep, and usually are not triggered by a precipitating stimulus or environment. Sometimes, a seizure may begin with the patients reporting an "aura" or warning. These subjective experiences might be described as a sense of déjà vu (a sense of reliving a familiar experience), a noxious smell, sudden anxiety, or tingling over one side of the body. Eyewitnesses might find the patients unresponsive to their direct questions, staring into space, or stopping what they were previously doing (behavioral arrest). Some patients exhibit oral or manual automatisms (lip smacking, chewing, rubbing of their hands, picking at their clothes). If a focal seizure then secondarily generalizes (electrical activity starting off in one area of the brain but then spreading to both hemispheres of the brain), the patients' head and eyes may suddenly and forcibly turn to one side, with stiffening of the limbs, frothing at the mouth, cyanosis of the lips, followed by rhythmic jerking of the limbs. Most secondarily generalized seizures last between 1 and 2 minutes in duration and rarely over 5 minutes in duration, but afterward, the patients may be confused and disoriented for minutes to hours. Patients may report lateral tongue biting and urinary incontinence after some seizures.

Clinical Features of Other Spells Potentially Mistaken for Syncope

Vertebrobasilar Transient Ischemic Attack

Transient ischemic attack (TIA) of the vertebrobasilar system is an extremely rare cause of brief loss of consciousness. The underlying pathophysiology is believed to be due to temporary ischemia of the brainstem reticular activating system. Almost invariably, TIAs of the vertebrobasilar system are associated with focal neurologic symptoms due to ischemia of the brainstem, cerebellum, and/or occipital lobe. Therefore, patients and family members will typically describe associated dysarthria, diplopia, dysphagia, hemianopsia, ataxia, unilateral weakness, or numbness.

Hypoglycemia

Hypoglycemia may cause feelings of light-headedness or dizziness and rarely results in a brief loss of consciousness. A more typical presentation of hypoglycemia is a slow and insidious onset of delirium that may last minutes to hours and be associated with diaphoresis, hunger, tremulousness, anxiety, and palpitations. If severe enough, hypoglycemia can progress to coma (otherwise, prolonged unresponsiveness) and/or generalized tonic-clonic seizures.

Basilar Migraine

Basilar migraine may cause confusion but rarely leads to loss of consciousness. It is associated with headache, ataxia, and positive visual phenomenon developing over minutes to hours and therefore is unlikely to be confused with syncope.

Subclavian Steal Syndrome

Subclavian steal syndrome is characterized by a reversal of blood flow in the vertebral artery, away from the brain, in order to supply blood flow to an ischemic arm. In this syndrome, exercising the affected arm leads to dizziness, vertigo, dysarthria, dysphagia, ataxia, unilateral weakness, and sometimes loss of consciousness.

Focused Physical Examination

If the clinician remains uncertain whether the diagnosis is syncope or seizure after taking the history, the physical examination is unlikely to be helpful. In cases of likely syncope, orthostatic blood pressure and auscultation of the neck and heart should be included as part of the routine physical examination and patients should have a routine 12-lead electrocardiogram (ECG).

Carotid sinus massage has been recommended in the evaluation of unexplained syncope in individuals older than age 45 years, but the procedure is generally not performed by neurologists. The generally accepted protocol for carotid sinus massage involves longitudinal massage at the region where the common carotid bifurcates, but the duration of massage should not last longer than 5 seconds and the force applied should not occlude the carotid artery. The procedure should be performed in upright and supine positions with continuous ECG and noninvasive blood pressure monitoring. The procedure should not be performed in individuals with known carotid disease, history of TIA or stroke within the last 3 months, or carotid bruit.

The *active standing test* (having the patient move from lying position to standing position) with simultaneous intermittent manual blood pressure monitoring (sphygmomanometer) may be helpful in diagnosing orthostatic hypotension. The test is considered diagnostic if there is a greater than 20 mm Hg decrease in systolic blood pressure and/or greater than 10 mm Hg decrease in diastolic blood pressure and/or decrease in systolic blood pressure <90 mm Hg within 3 minutes of standing and the patient is symptomatic. Initial orthostatic hypotension is defined as a blood pressure decrease immediately on standing of

TABLE 6.3 "Red Flags": When to Consider a Diagnosis of Cardiac Syncope

Clinical features	• Lack of clear trigger causing syncope • Absence of sweating/nausea before syncope • Syncope while supine • Palpitations at the time of syncope • Syncope with exercise/effort
Demographic features	• Older age • Family history of sudden death • Personal history of structural heart disease • Fewer events (less than three syncopal events)

greater than 40 mm Hg, whereas delayed orthostatic hypotension is described as a slow, progressive decline in systolic blood pressure while standing.

Diagnostic Tests

In rare circumstances, if the diagnosis of seizure or syncope remains unclear and the events are frequent and relatively easy to replicate, simultaneous video/electroencephalography and ECG can be performed to characterize these events.

Once the diagnosis of syncope has been established but the cause remains uncertain (unlikely reflex syncope or orthostatic hypotension), further laboratory studies to consider might include hemoglobin/hematocrit to look for anemia, chemistry panel to look for electrolyte disturbances, tilt table testing to try to reproduce neurally mediated reflex syncope, echocardiography to evaluate cardiac structure and function, and/or continuous ECG monitoring to investigate the possibility of a cardiac arrhythmia. The decision to pursue further cardiac testing (continuous ECG monitoring or echocardiography) should be strongly considered if there is any suspicion of a potential cardiac cause (Table 6.3). More systematic, protocol-based approaches attempting to stratify high-risk patients have failed to perform consistently when tested in varying patient populations, but expert consensus recommends prompt hospitalization and immediate evaluation for patients with abnormal 12-lead ECG findings, known severe cardiac disease, severe anemia, electrolyte disturbances, and/or clinical features concerning for cardiac syncope (Table 6.4). In older individuals with suspected orthostatic hypotension that is not immediately demonstrated on the active standing test, 24-hour ambulatory blood pressure monitoring should be considered, especially if postprandial or early morning blood pressure instability is a consideration.

TABLE 6.4 "Red Flags": When to Consider Prompt Hospitalization or Intensive Evaluation

Clinical features	• Severe cardiac structural dysfunction or coronary artery disease • Family history of sudden cardiac death • Syncope during exercise or while supine • Palpitations at the time of syncope
Comorbidities	• Severe anemia • Electrolyte disturbance
Abnormal ECG findings	• Bifascicular block or other intraventricular conduction block (QRS duration >120 ms) • Inadequate sinus bradycardia (<50 beats/min) in absence of negative chronotropic medication or physical training • Prolonged or short QT interval • Right bundle branch block with ST elevation in leads V_1 to V_3 (Brugada pattern) • ECG pattern suggestive of arrhythmogenic right ventricular cardiomyopathy

Abbreviation: ECG, electrocardiogram.

MANAGEMENT

For patients with vasovagal syncope and orthostatic intolerance, nonpharmacologic management strategies are most effective. Patients benefit greatly from education about the condition, identification and then avoidance of potential triggers, and learning how to perform maneuvers to abort an episode (supine posture; physical counterpressure maneuvers consist of leg crossing, arm tensing, or hand grip).

For patients with orthostatic hypotension, avoiding offending drugs (antihypertensives, diuretics, tricyclic antidepressants, and alcohol) is the first step. Sleeping with the head of the bed at 10° reduces some nocturnal hypertension and polyuria, and compression stockings should also be considered.

Management of syncope in the setting of cardiovascular disease is beyond the scope of this chapter, and patients should be referred to cardiology.

If the events are recurrent and clear triggers have not been identified, patients should be counseled about high-risk activities such as driving, operating heavy machinery, and working at unrestricted heights, and in some states, mandatory reporting is required.

OUTCOME

Prognosis and outcome measures center around two main considerations:

1. Risk of death and life-threatening events. The prognosis is largely dependent on the underlying cause. For young persons with reflex syncope and absence of any electrical or structural heart disease, the prognosis is excellent. Older individuals with orthostatic hypotension are 2 times more likely to die because of associated comorbid medical conditions. Structural and electrical heart diseases are also associated with increased mortality; the degree of risk is largely dependent on the severity of the underlying cardiac disease.
2. Syncope recurrence and physical injury. Approximately 30% of patients experience a recurrence of syncope in the following 3 years, and the recurrence risk increases with the total number of lifetime events. Risk of physical injury due to syncope appears to increase with age and absence of prodromal symptoms.

7 Seizures

Michelle Bell, David J. Roh, and Jan Claassen

KEY POINTS

1. Treat early with benzodiazepines as first-line therapy; agent of choice is intravenous lorazepam.
2. Continue therapy with second-line or urgent control therapy with phenytoin/fosphenytoin or valproic acid, alternatives include levetiracetam, phenobarbital, or lacosamide.
3. Start maintenance of antiepileptic drug therapy after second-line or urgent control therapy.
4. If the patient does not return to baseline within 20 minutes after convulsions stop, suspect nonconvulsive seizures or status epilepticus.
5. Continuous electroencephalogram must be ordered to further drive therapeutic management of status epilepticus.
6. If there is evidence of prolonged seizures, intubate and escalate to continuous intravenous anesthetic antiepileptic drug agents.
7. Do not delay treatment.

INTRODUCTION

Seizures are frequently encountered in both the community and hospital setting. Epidemiologic studies in the United States have shown that 11% of the general population will have a seizure at some point in their life. There is an estimated 1 million hospital visits due to seizures per year.

On a cellular level, neurons communicate via action potentials, and a seizure is the result of excessively synchronized action potentials that are not stopped by the brain's normal inhibitory processes. On a clinical level, the International League Against Epilepsy (ILAE) defines seizures as transient clinical events due to abnormally excessive or synchronous neuronal activity in the brain. Seizures can be focal or generalized in onset and have a wide range of manifestations including cognitive, autonomic, sensory, and motor symptoms (**Fig. 7.1**).

A failure to stop isolated seizures may lead to status epilepticus (SE). Its incidence has increased in recent years with 5 to 30 cases per 100,000. SE is defined as seizures lasting more than 5 minutes, or 2 or more seizures in a 5-minute interval without a return to preseizure neurologic baseline. Historically, SE had been defined as continuous seizure activity lasting greater than 30 minutes without complete recovery. However, the minimum time elapsed to qualify for SE was shortened to 5 minutes based on the observation that isolated seizures rarely last for more than a few minutes and that irreversible brain injury can occur as early as 5 minutes of ongoing seizure activity. Furthermore, isolated seizures that are of longer duration typically do not stop spontaneously. Delaying effective recognition and treatment of SE dramatically increases the patient's morbidity and mortality.

SE constitutes a neurologic emergency requiring prompt and decisive intervention. This chapter focuses on the initial diagnostic workup and management of seizures and SE.

MANAGEMENT STRATEGY

Management is focused on controlling the seizures as quickly as possible by escalating therapy. The most common management error in the management of SE is underdosing and failure to escalate therapy in a timely fashion. An overview of the various steps in initiating and escalating therapy is shown in **Table 7.1**.

FIGURE 7.1 Classification of seizure types. (Derived from Fisher RS, Cross JH, French JA, et al. Operational classification of seizure types by the International League Against Epilepsy: position paper of the ILAE Commission for Classification and Terminology. *Epilepsia*. 2017;58[4]:522-530. doi:10.1111/epi.13670.)

TABLE 7.1 Overview of Management for Seizures and Status Epilepticus

[ ] Diagnose: by history, exam, or EEG
[ ] Airway, breathing, circulation: Assess and stabilize.
[ ] Emergent initial treatment: benzodiazepines (see **Table 7.4**)
[ ] Second-line urgent control treatment: phenytoin, valproic acid, levetiracetam, or phenobarbital (see **Table 7.5**)
[ ] Seizure workup: Look for provoking factors concurrently with other steps.
[ ] Maintain baseline AEDs: Check levels and rebolus if IV formulations exist.
[ ] If seizures persist: Obtain cEEG; intubate for refractory status epilepticus.
[ ] Refractory status epilepticus: cIV pentobarbital, propofol, midazolam, ketamine

Abbreviations: AEDs, antiepileptic drugs; cEEG, continuous electroencephalogram; cIV, continuous intravenous; IV, intravenous; SE, status epilepticus.

TABLE 7.2 History Taking for Seizures

Likelihood of This Being Seizure

- History elements concerning for:
  - Syncope: history of syncope, brief duration of the loss of consciousness, asynchronous myoclonic jerks, occurrence while standing
  - Psychogenic nonepileptic attack: occurrence in the setting of an emotional trigger, eye closure during the episode, horizontal head movement, asynchronous limb jerking, waxing and waning of symptoms in the course of one episode
  - Cateplexy: a history of narcolepsy, loss of tone without loss of consciousness, a strong emotional trigger for the episode
  - Limb-shaking transient ischemic attack: history of carotid stenosis contralateral to the movements, arrhythmic movements
  - Seizures: history of seizures, abrupt offset and onset, postepisode weakness or confusion, history of head trauma, febrile seizures, developmental delay, or family history of seizures

Provoking Factors

- In patients with a history of seizures ask about factors that can lower the seizure threshold such missed antiseizure medications and sleep deprivation.
- Query about situations that can lead to acute symptomatic seizures.

Primary Generalized or Focal Onset

- Ask if the patient had warning or an "aura."
- Ask the patient and bystanders if there were any lateralizing features before, during, or after the seizures. Specifically ask if motor symptoms were noticed first on one seizure of the body and if the weakness was noted on one side of the body after the seizure ("Todd paralysis").
- Localizing features of seizures (ie, hemifield visual aura: contralateral occipital lobe; clonic activity: contralateral motor strip; "figure-of-four": contralateral SMA; unilateral dystonic posturing: contralateral activation of basal ganglia)

Features of Status Epilepticus

- Seizure lasting more than 5 min
- If there has been a lack of return to neurologic baseline, the patient might be in convulsive status epilepticus especially if the clinical seizure preceding this unresponsiveness was >5 min.

Abbreviation: SMA, supplementary motor area.

INITIAL DIAGNOSIS

The diagnosis of a seizure is often made based on the symptoms or signs reported by the patient, bystanders, or clinicians. The symptoms/signs of a seizure are often referred to as the *semiology*. As detailed in the ILAE seizure classification, seizures can manifest as excess activity ("positive" symptoms) or lack of activity ("negative" symptoms). The positive symptoms can obvious and include rhythmic jerking or dystonic posturing, or can be subtle with symptoms of twitching, nystagmus, automatisms, and eye deviation. Negative symptoms of seizures include staring, coma, lethargy, confusion, and aphasia.

Nonconvulsive seizures are common in the critical care setting with incidences ranging from 5% to 40%. If seizures or SE are suspected based on preliminary clinical assessment, the clinician should proceed with a focused history and exam. A focused assessment will prevent delayed initiation of appropriate management, which can significantly increase the likelihood of morbidity and possibly mortality.

History

The goals of the focused history are to (1) assess the likelihood that this presentation is due to seizures, (2) ascertain whether there are any provoking factors, (3) determine if this was a primary generalized seizure or a focal seizure with or without secondary generalization, (4) localize the likely seizure focus if focal, and (5) determine if the patient is having ongoing seizure activity or SE (**Table 7.2**).

Exam

A focused general physical exam should rapidly screen the patient's clinical stability and identify life-threatening etiologies of seizures. These may include meningitis, intracranial hemorrhage, ischemic stroke, or any other type of acute intracranial mass effect. Vital signs should be monitored with particular attention to hemodynamic stability and respiratory status. Focus should be paid to the presence of fever, nuchal rigidity, and rash. These findings, if present, should raise suspicion for a central nervous system infection prompting further laboratory investigation and empiric antibiotic treatment. Skin findings can be suggestive of meningitis, but might also be indicative of an underlying neurocutaneous disease such as tuberous sclerosis (ie, ash-leaf spots or shagreen patches) or neurofibromatosis (ie, café au lait macules or neurofibromas). Such neurocutaneous diseases often cause both skin findings as well as seizures.

Observation and gross neurologic examination may detect obvious positive symptoms of seizures supporting the diagnosis. These symptoms can be obvious or subtle. Absence of obvious symptoms should not preclude the possibility of seizures. Nearly half of patients with generalized tonic clonic SE will continue to have electrographic seizures after convulsions have stopped. In these cases, the diagnosis of SE can only be made by electroencephalogram (EEG) monitoring.

Differential Diagnosis

The differential diagnosis for seizures and SE include but are not limited to movement disorders, limb-shaking transient ischemic attacks, convulsive syncope, posturing, sleep disorders, transient global amnesia, complicated migraine, and psychiatric

nonelectrographic seizure activity. The differential for nonconvulsive SE is much broader and can mimic anything that would result in impairment of consciousness ranging from toxic metabolic encephalopathy to anoxia or infections.

Causes of Seizures: Provoked Seizures, Unprovoked Seizures, and Lowered Seizure Threshold

It is important to identify any underlying cause for seizures as management will be tailored accordingly. In classifying the cause of seizures, it is important to elucidate whether the seizure was provoked. A "provoked" seizure generally occurs in the context of acute brain injury, systemic toxic—metabolic insult, illicit drug use, or medications known to lower seizure threshold (Table 7.3). The ILAE uses the term *acute symptomatic seizures* to refer to all provoked seizures and defines these as seizures that occur within the first 7 days of brain injury (eg, cerebrovascular disease, traumatic brain injury, intracranial surgery, and central nervous system infections), in the context of alcohol or drug (medication or illicit) use that is known to trigger seizures, during a febrile illness, or in the context of metabolic derangement (eg, serum glucose <36 mg/dL or >450 mg/dL associated with ketoacidosis, serum sodium <115 mg/dL, serum calcium <5.0 mg/dL, serum magnesium <0.8 mg/dL, urea nitrogen <100 mg/dL, creatinine >10.0 mg/dL).

Of note, some authors, like the ILAE, use the terms *provoked seizure* and *acute symptomatic seizure* interchangeably, whereas other authors use the term *provoked seizures* when referring to seizures secondary to toxic-metabolic insults and "acute symptomatic seizures" to describe those that occur in the context of acute brain injury. The reason for this distinction is that seizures caused by a metabolic disturbance, offending medication, or drug potentially carry a lower risk of seizure recurrence than those that occur in the context of an acute brain injury. In provoked seizures with a clearly identifiable trigger (ie, severe metabolic disturbance or offending drug), the clinical practice is to not start antiepileptic drugs (AEDs). However, with the risk of seizure recurrence after acute brain injury being between 13% and 33%, there are subsequently mixed views on the necessity of starting long-standing preventative AEDs. Some centers start AEDs in this setting acutely with the long-term plan to wean these mediations off in the outpatient setting given the potentially decreased risk of seizures over time. Ongoing studies are actively looking at the long-term risk of developing epilepsy after acute brain injury.

Unlike the low rate of recurrent late seizures seen with provoked seizures, the rates of recurrent seizures can be as high as 70% in some patients with unprovoked seizures. In patients with unprovoked seizures, it is important to identify this subset of high-risk patients and start antiepileptic treatment. This can be done by assessing for epileptiform discharges on the EEG and focal abnormalities on the magnetic resonance imaging (MRI). If either of these are present, patients meet the 2014 ILAE criteria for epilepsy and should be advised to start an AED. If the patient carries a diagnosis of epilepsy, factors that lowering the seizure threshold should be determined. Some common factors include low AED levels due to medication, noncompliance or drug interactions, recent changes in AEDs, sleep deprivation, high stress levels, menstruation, or mild to moderate systemic infection.

TABLE 7.3 Drugs That Lower Seizure Threshold

• Analgesics: narcotics (tramadol, fentanyl, meperidine)
• Antibiotics: penicillins, imipenem, cephalosporins, isoniazid, metronidazole
• Anticholinesterases
• Antidepressants: bupropion, tricyclics
• Antihistamines: diphenhydramine
• Antipsychotics: clozapine, phenothiazine
• Chemotherapy: etoposide, cisplatinum

EMERGENT MANAGEMENT

Prehospital Stabilization and Treatment

Perhaps, the most important factor in the treatment of acute seizures is the amount of time it takes to administer the initial treatment. This requires a timely recognition of seizures by bystanders and notification of emergency medical services (EMS). Prehospital EMS care with patient stabilization and medication administration is vital in early treatment of acute seizures and has been associated with improved patient outcomes. Stabilization includes initial assessment of secure airway, stable breathing, and circulation. Once stabilized, prehospital care also involves attempts at obtaining intravenous (IV) access and assessing for reversible causes of seizures such as hypoglycemia.

Following initial assessment, treatment for convulsive seizures can be given by EMS (Table 7.4). Benzodiazepines have been the AED of choice in the field and are considered first-line treatment options for seizures. IV agents have traditionally been used with lorazepam (4 mg) or diazepam (10 mg). In appropriate, targeted dosing, seizure patients that receive IV benzodiazepines have lower instances of respiratory depression/intubation than patients that have prolonged seizures without treatment. IV benzodiazepines, particularly IV lorazepam, have been found to be safe and efficacious in early prehospital

TABLE 7.4 Emergent First-Line Therapy Benzodiazepine Agents and Dosing[a]

Benzodiazepine	Route	Dosing
Lorazepam	IV	0.1 mg/kg IV (max 4 mg per dose) and can repeat at 5-10 min
Diazepam	IV	0.15 mg/kg IV (max 10 mg per dose) and can repeat in 5 min
	PR	0.2 mg/kg PR for >12 y
		0.3 mg/kg PR for 6-11 y
		0.5 mg/kg PR for 2-5 y
Midazolam	IM	0.2 mg/kg IM (max 10 mg)
	Intranasal	0.2 mg/kg intranasal
	Buccal	0.5 mg/kg buccal

Abbreviations: IM, intramuscular; IV, intravenous; max, maximum; PR, per rectum.

[a]Adapted from Brophy GM, Bell R, Claassen J, et al; for Neurocritical Care Society Status Epilepticus Guideline Writing Committee. Guidelines for the evaluation and management of status epilepticus. *Neurocrit Care*. 2012;17(1):3-23.

treatment of convulsive seizures LEVEL 7.[1] Despite its efficacy, its use has been limited due to the difficulty of obtaining IV access in a seizing patient and the challenges surrounding storage of IV lorazepam in ambulances. As a result, intramuscular (IM) midazolam (10 mg) has been increasingly used in the prehospital setting and has shown to be an effective alternative to IV lorazepam LEVEL 7.[2]

Hospital Stabilization and Treatment

Once the patient arrives to the hospital, he or she should once again be assessed for stable airway, breathing, and circulation. Supplemental oxygen can be provided. Hemodynamic monitoring should be implemented with particular attention to blood pressure, cardiac monitoring, and oxygenation. IV access, if not already established, should be obtained along with fluid resuscitation to maintain euvolemia.

Physicians should reassess glycemic status, and if there is evidence of hypoglycemia, it is important to promptly treat with Dextrose 50 in water (D50W) 50 mL IV with concurrent thiamine 100 mg IV. Handoff between EMS services and physicians should establish what treatments were given in the field, including benzodiazepine doses.

Initial first-line benzodiazepine therapy is frequently underdosed as seizure dosing is higher than most indications seen by EMS or emergency department providers. Attention should be made to provide full appropriate benzodiazepine treatment via additional doses, if not given initially. Lorazepam IV has been shown to be the preferred initial agent LEVEL 7.[3] A recommended total dose of 0.1 mg/kg (4 mg per dose) can be given. A repeat dose of 4 mg can be given after 5 to 10 minutes if needed (for a maximum total dose of 8 mg). Lorazepam should be administered at a rate up to 2 mg/min. Close attention should be taken to cardiopulmonary status during benzodiazepine administration to avoid uncontrolled hypotension or respiratory depression. Similar to the prehospital management, if there is no IV access readily available, benzodiazepines can be administered via IM, rectal, nasal, or buccal routes. Midazolam is the preferred agent for IM administration. This can be administered at 0.2 mg/kg IM for a total dose of 10 mg (see **Table 7.1**).

Initial Workup

Although emergent management is underway, concurrent diagnostic workup should be pursued (**Table 7.5**). All patients should receive serum laboratory evaluation with complete blood count, basic metabolic panel, liver function tests, and AED levels. Patients should also receive urine drug toxicology testing to evaluate for any metabolic etiologies of seizures. On admission, a noncontrast computed tomography of the brain should be performed to screen for any obvious structural etiologies of seizures.

The extended workup, to be chosen on a case-by-case basis, includes a lumbar puncture, brain MRI, and further laboratory tests (eg, paraneoplastic panel). If there is a concern for infection—the patient is febrile, there is a serum leukocytosis or nuchal rigidity on exam—then a lumbar puncture is warranted. The lumbar puncture should not delay empiric meningitis treatment if suspected. A brain MRI is often pursued if the initial noncontrast head computed tomography is negative, especially if there are focal features with the seizure, exam or on EEG. A paraneoplastic panel is often obtained in the case of new-onset refractory SE (RSE), new-onset bitemporal epilepsy, and in any presentation otherwise concerning for a paraneoplastic syndrome.

TABLE 7.5 Admission Orders for Status Epilepticus[a]

Perform immediately in ED and concurrently with emergent management and treatment

All Patients

- Glucose fingerstick
- Hemodynamic monitoring and vital signs (blood pressure, cardiac monitoring, O_2 saturation, heart rate)
- Neuro checks
- IV access
- O_2 administration (if needed)
- Head CT scan
- Serum lab test: complete blood count, basic metabolic panel, blood glucose, liver function tests, calcium (total and ionized), magnesium, troponin, antiepileptic drug levels, toxicology screen (cocaine and urine), pregnancy test (if female)
- Stat EEG

Consider Depending on Presentation

- Brain MRI
- Lumbar puncture
- Comprehensive toxicology panel: toxins that frequently cause seizures (isoniazid, tricyclic antidepressants, theophylline, sympathomimetics, organophosphates, cyclosporine)
- Serum blood work: type and screen, coagulation studies, arterial blood gas, inborn errors of metabolism, paraneoplastic workup

Abbreviations: CT, computed tomography; ED, emergency department; EEG, electroencephalogram; IV, intravenous; MRI, magnetic resonance imaging; O_2, oxygen; stat, immediately.

[a]Adapted from Brophy GM, Bell R, Claassen J, et al; for Neurocritical Care Society Status Epilepticus Guideline Writing Committee. Guidelines for the evaluation and management of status epilepticus. *Neurocrit Care*. 2012;17(1):3-23.

Indications for Hospital Admission

Typically, emergency department policy states that patients with a normal neurologic examination following a seizure can be discharged from the emergency department with outpatient follow-up. However, if the patient fails to return to baseline in 10 minutes, SE should be suspected, and admission is warranted. Failure to control convulsive seizures or persistent unexplained altered mental status requires further evaluation with a continuous EEG (cEEG). These patients with suspected SE require admission to an intensive care unit for further EEG directed treatment and hemodynamic monitoring. cEEG monitoring should be established within 1 hour of suspected SE and maintained for at least 48 hours in comatose patients to detect nonconvulsive seizures.

STATUS EPILEPTICUS

Second-Line Therapy

In patients with SE or prolonged seizures, the timely administration of second-line (or "urgent control") therapy is vital (**Fig. 7.2**). Second-line therapy administration should ideally occur concomitantly with first-line benzodiazepine therapy.

FIGURE 7.2 Status epilepticus algorithm. Abbreviations: AED, antiepileptic drug; BP, blood pressure; cEEG, continuous encephalogram; cIV, continuous intravenous; D50W, Dextrose 50 in water; ICU: intensive care unit; IM, intramuscular; IV, intravenous; O2, oxygen; RSE, refractory status epilepticus.

EMERGENT MANAGEMENT
1. Recognition and diagnosis of prolonged seizures
2. Stabilize patient: ABCs (airway, breathing, circulation). Place IV, supplemental O_2, and hemodynamic monitoring.
3. Thiamine 100 mg and D50W 50 mL IV (if hypoglycemia)
4. Lorazepam 4 mg over 2 min IV; can repeat after 5 min if still seizing; midazolam 10 mg IM or diazepam 20 mg per rectum if no IV route available
5. Monitor BP and respiratory status during treatment. If no, return to baseline:

↓

SECOND LINE THERAPY/URGENT CONTROL THERAPY
1. Fosphenytoin 20 mg/kg IV at 150 mg/min or valproic acid 40 mg/kg IV over 10 min
2. Can consider levetiracetam 1-3 g IV over 2-5 mg/kg/min
3. Start maintenance dose of loaded AEDs and order AED levels postloading.
4. Order cEEG unless patient is clearly back to baseline.
5. Can consider giving additional fosphenytoin 5-10 mg/kg IV × 1 vs valproic acid 20 mg/kg IV × 1 if no improvement or continued seizure activity. However, do not perform this at the expense of delaying more aggressive RSE treatment measures.
6. Monitor BP and respiratory status during treatment. Consider intubation if sedation or seizure compromises airway. If no improvement:

↓

REFRACTORY STATUS EPILEPTICUS
1. Intubate patient and admit to the ICU.
2. cEEG should be in place.
3. RSE cIV anesthetic agents to goal of burst suppression: See table for RSE medications.
4. Monitor hemodynamic stability and add vasopressors if needed.
5. Monitor cEEG for 24-48 h for seizure suppression and optimize maintenance AED.

Benzodiazepine therapy alone has a short duration of treatment effect and will not be effective in preventing prolonged seizures or SE. There is no need to delay the administration of second-line therapy to assess if the patient responds to first-line benzodiazepine therapy. The goal of second-line/urgent control therapy is to establish rapid therapeutic levels.

Frequently used second-line agents include phenytoin/fosphenytoin, valproic acid, phenobarbital, levetiracetam, and lacosamide. Prospective studies have not revealed a superior second-line AED agent. The Established Status Epilepticus Treatment Trial compared efficacy of phenytoin, valproic acid, and levetiracetam in generalized convulsive SE demonstrated similar efficacy with each drug; lorazepam and phenytoin (20 mg/kg) controlled seizures in 45% of patients, lorazepam and valproic acid (40 mg/kg) controlled seizures in 46% of patients, and lorazepam and levetiracetam (60 mg/kg) controlled seizures in 47% of patients LEVEL 1.[4] Due to long-standing familiarity with phenytoin's efficacy in SE, fosphenytoin/phenytoin is commonly used as the second-line therapy of choice. A 20 mg/kg IV can be given with either formulation. Fosphenytoin can be given at rate of 150 mg/min and phenytoin at 50 mg/min. Care must be taken to avoid rapid infusion because this may cause hypotension or arrhythmias. Fosphenytoin has a lower rate of cardiac toxicity and local tissue injury. Despite some institutional preference for phenytoin use, data suggests IV valproic acid is of equal efficacy and can be given at a rate of 20 to 40 mg/kg IV over 10 minutes with an option of giving an additional 20 mg/kg over 5 minutes if seizure activity continues. If levetiracetam IV is chosen, the recommended dose is 60 mg/kg with administration rate of 2 to 5 mg/kg/min IV. Most recently, lacosamide at loading doses of 50 to 400 mg has been shown to be also effective at aborting SE with overall efficacy of 57%.

After second-line or urgent control therapy is administered, AED maintenance therapy is required even if seizures are controlled. This requires giving maintenance doses of the AED that was administered IV. In spite of current guideline recommendations of utilizing second-line intermittent IV AED therapy in cases of SE, many experts advocate for more aggressive treatment of SE. Rather than treating with second-line intermittent IV AEDs, waiting for a clinical response, and reloading with these agents, many clinicians favor proceeding directly to continuous IV (cIV) infusion anesthetic agents while concomitantly using intermittent IV second-line AEDs. Studies have shown suboptimal cessation of seizure activity with the sole use of classic intermittent IV second-line agents such as phenytoin. Consequently, when possible, the aggressive escalation of treatment straight to cIV anesthetic AEDs such midazolam can be considered (see Fig. 7.2).

Refractory Status Epilepticus and Anesthetic (Third-Line) Treatment

If there is failure to control SE after the use of a benzodiazepine and second-line AED, the patient is considered to be in RSE. RSE occurs in approximately 30% of patients with SE and is associated with increased morbidity and mortality. The pathophysiology of propagation to RSE involves the internalization of γ-aminobutyric acid receptors and upregulation of excitatory *N*-methyl-D-aspartate (NMDA) receptors. Management of RSE requires rapid and aggressive escalation of care with intubation (if not already performed) and induction of coma with cIV anesthetic agents with therapeutic targets at these two receptors. It is unclear of the treatment target endpoints because some evidence suggests that RSE outcome is based on the underlying cause of

TABLE 7.6 Continuous Intravenous Anesthetic Agents for Refractory Status Epilepticus

Drug	Bolus Dose	Maintenance Dose	Side Effects
Midazolam	• 0.2 mg/kg (rate of 2 mg/min)	• 0.05-2.9 mg/kg/h	• Respiratory depression
Propofol	• 1-2 mg/kg over 3-5 min • Repeat bolus every 3-5 min until seizures stop (maximum 10 mg/kg).	• 30-100 μg/kg/min	• Hypotension • Propofol infusion syndrome (particularly at >80 μg/kg/min for >48 h)
Ketamine	• 1.5-4.5 mg/kg IV	• 2.75-5 mg/kg/h	• Hypertension and tachycardia
Pentobarbital	• 5-15 mg/kg (up to 50 mg/min)	• 1-10 mg/kg/h	• Hypotension • Ileus

Abbreviations: IV, intravenous; NMDA, *N*-methyl-D-aspartate.

RSE rather than the aggressiveness of treatment. Despite this, many experts agree that aggressive treatment tailored to EEG suppression in addition to suppression of clinical seizure activity. This suppression should be pursued with cIV agents. cEEG is vital at this point in both evaluating for seizure activity and response to therapy.

Although there is no uniform consensus on optimal RSE therapy, frequently used third-line agents include midazolam, propofol, and pentobarbital (Table 7.6). For superrefractory SE, defined as seizures that persist after 24 hours of continuous infusion anesthetic therapy, the addition of ketamine to midazolam is an increasingly popular alternative to pentobarbital. There remains a paucity of prospective comparative studies for these agents. However, retrospective analysis and limited prospective studies have given some guidance for future studies and selection of preferred RSE treatments.

Pentobarbital has been seen to have higher treatment efficacy compared to propofol and midazolam. However, longer rates of mechanical ventilation have been seen with barbiturate use due to its long half-life along with increased risk of cardiac side effects. Pentobarbital infusion is preceded by a loading dose of 5 to 15 mg/kg (up to 50 mg/min) with repeated boluses of 5 mg/kg until seizure suppression is achieved. Maintenance infusion can be started at 0.5 to 1 mg/kg/h with titration up to 10 mg/kg/h for goal of either seizure or EEG burst suppression.

Propofol is also an effective agent, but it requires careful hemodynamic monitoring. It can cause hypotension along with propofol infusion syndrome (circulatory collapse, lactic acidosis, hypertriglyceridemia, rhabdomyolysis). Propofol requires a 1 to 2 mg/kg loading dose over 3 to 5 minutes.

Repeat boluses can be given every 3 to 5 minutes until seizures stop (maximum loading dose of 10 mg/kg). Maintenance propofol dosing should be titrated to seizure or EEG burst suppression at 30 to 200 μg/kg/min. Doses of greater than 80 μg/kg/min for extended periods of time (>48 h) may place the patient at risk for propofol infusion syndrome.

Midazolam appears to have less of an effect on blood pressure in comparison to propofol or pentobarbital. However, its use is particularly prone to tachyphylaxis, and its mechanism of action is hindered by not having any effect on NMDA receptor sites. Midazolam requires a loading dose of 0.2 mg/kg at a rate of 2 mg/min. Repeat boluses of 0.2 to 0.4 mg/kg boluses every 5 minutes can be given until seizures stop with a maximum loading dose of 2 mg/kg. Maintenance infusion can be titrated for goal of seizure or EEG burst suppression at 0.05 to 2.9 mg/kg/h. However, maintenance infusion rates of as high as 2.9 mg/kg/h can be used safely with lower rates of withdrawal seizures and lower discharge mortality rates.

Ketamine is another therapeutic measure sometimes used for SE. Ketamine is an NMDA receptor antagonist, given with a loading dose of 1 to 2 mg/kg IV every 1 minute, a maintenance dose of 0.01 to 0.03 mg/kg/min cIV. It is used in caution in patients with increased intracranial pressure, traumatic brain injury, intracranial mass, hypertension, chronic congestive heart failure, tachyarrhythmias, myocardial infarction, and alcohol history. In a multicenter case series, the addition of ketamine contributed to control of RSE in 32% of patients for which it was used. Although the mortality rate was 43%, this was lower when SE was stopped within 24 hours of starting ketamine (16% vs 56%).

Add-on therapeutic hypothermia was recently studied in patients with convulsive SE, and although it was associated with a lower rate of progression to EEG confirmed SE, it was not associated with improvement in functional outcome at 90 days or a decreased progression to superrefractory SE.

There is no clear support for the length of treatment and seizure suppression with IV anesthetic agents before weaning attempts are made. However, general consensus states that patients should remain seizure free for 24 to 48 hours on cEEG monitoring. While waiting for this to occur, the patient's maintenance AED agents should be optimized to therapeutic levels. Levels can be allowed to be supratherapeutic and should be dictated based on seizure control and side effect profile. When the patient has stabilized, gradual attempts can then be made to wean off these agents. Often, this is done outside the intensive care unit (on the hospital floor) or in the outpatient setting.

ELECTROENCEPHALOGRAM MONITORING DURING STATUS EPILEPTICUS

The EEG findings during monitoring of SE are complex. One reason for this is that the EEG evolves during a given episode of SE. As described by Treiman at in "A progressive sequence of electroencephalographic changes during generalized convulsive status epilepticus," there appears to be five EEG patterns that occur sequentially during the course of generalized SE: (1) discrete seizures, (2) merging seizures with waxing and waning amplitude and frequency of EEG rhythms, (3) continuous ictal activity, (4) continuous ictal activity punctuated by low voltage "flat periods," and (5) periodic epileptiform discharges on a "flat" background. The temporal time course of these five stages varies, and there is no enough data to establish normative values, but there has been a reported case of a patient progressing through all five stages in less than 24 hours.

The second reason for the EEG complexity is that patients who have SE often later have waveforms on the "ictal-interictal continuum." These are waveforms that are not definitely seizures based on American Clinical Neurophysiology Society's Standardized Critical Care EEG Terminology criteria but have many features of seizures and are thought to represent possible ongoing underlying neuronal injury. Depending on the clinical situation, patients with these patterns are given a dose of a short-acting benzodiazepine or an AED to see if the EEG pattern and clinical exam improves.

The third reason for this complexity in the EEGs of patients with SE is that there are usually frequent to abundant epileptiform discharges. Studies have demonstrated that some of these discharges—lateralized periodic discharges, bilateral independent periodic discharges, and generalized periodic discharges—are associated with an increased incidence of seizures, particularly when there are superimposed fast activity, rhythmic activity, sharp waves, or spikes. Of note, there is evidence that periodic discharges with a frequency of greater than 2.0 Hz is associated with focal brain hypoxia. Because this is the same physiologic consequence of seizures, discharges of this frequency or greater can be clinically treated as seizures even in the absence of electrographic evidence of evolution.

Given the wealth of information that can be obtained from the EEG, placement of the EEG should not be delayed if there is a high clinical suspicion for seizures or SE.

Pain, Numbness, and Paresthesias 8

Comana M. Cioroiu

KEY POINTS

1. Characterize the nature of the complaint—what does the patient mean by "numbness"? How can you characterize the pain?
2. Obtain a detailed history and examination to help localize the patient's complaints of numbness/paresthesias to a location in either the central or peripheral nervous system.
3. When examining a patient with sensory loss, look for asymmetry, a distal versus proximal gradient, and try to identify a pattern of sensory loss to guide your diagnostic impression.
4. Look out for red flags that suggest an urgent problem that needs to be addressed and treated rapidly.
5. Let your differential diagnosis guide your diagnostic testing.
6. Treatment of chronic pain and paresthesias can be complex and often requires a multidisciplinary approach.

INTRODUCTION

For the general neurologist, the evaluation of a patient with complaints of numbness can be a daunting one. Being the most subjective of neurologic complaints, numbness is often a difficult sensation for the patient to explain and often all the more difficult for the clinician to appreciate on examination and may be referable to a problem in either the central or peripheral nervous system. Numbness may also be a subjective complaint in patients with various chronic pain syndromes and certain psychiatric conditions in which cases the etiology is nonneurologic and often has no physiologic basis.

MANAGEMENT STRATEGY

As with all complaints in medicine, the first step is to obtain a detailed history. The first question should be one aimed at best characterizing the sensation (or lack thereof) described by the patient. It is important to differentiate between numbness as a *loss of sensation* as opposed to the *presence of an abnormal sensation*. At times, patients may also use the term *numbness* to describe muscle weakness, and this is important to keep in mind during one's examination.

Types of Sensory Symptoms

Numbness can occur as a result of pathology at several different parts of the neuraxis, including the cortex, brain stem, spinal cord, and peripheral nerves. *Paresthesias*, spontaneous and abnormal sensations often described as "tingling" or "pins and needles," may imply a different neurologic localization than a complete lack of sensation alone. They also may occur following a period of absent sensation as nerves begin to slowly regenerate. Certain types of sensory seizures may also present with such sensations.

Neuropathic Pain

Neuropathic pain (see Chapter 59) is a category of pain specific to that caused by nerve injury and is often described as painful paresthesias, associated with a sensation of burning or radiating pain as can be seen in cases of peripheral neuropathy or radiculopathy (Fig. 8.1). In such cases, patients may exhibit altered sensation or abnormally increased sensations—*hyperesthesia* refers to increased sensation, whereas *dysesthesia* refers to an evoked unpleasant or painful sensation by an otherwise innocuous stimulus.

An exaggerated response to stimuli that normally evoke pain is known as *hyperalgesia*, whereas an exaggerated and extreme pain response to stimuli that should not normally invoke pain is referred to as *allodynia*. These abnormal sensations can be seen with various nerve injuries, both at the central and peripheral level. Conversely, *hypoesthesia* refers to the diminished perception of pain, *anesthesia* to the inability to perceive pain, and *analgesia* to the inability to feel pain.

Neuropathic pain must be differentiated from somatic pain caused by pathology in bones, ligaments, muscles, and other soft tissues.

Complex regional pain syndrome (also known as *reflex sympathetic dystrophy*) is a chronic disease characterized by severe neuropathic pain, skin changes, and swelling in one limb. It may occur in the absence of a known nerve injury (type 1) or in the setting of known nerve injury (type 2). Diagnosis and treatment of complex regional pain syndrome is further discussed in Chapter 58.

NEUROANATOMY AND LOCALIZATION

The pattern and distribution of sensory complaints provides important clues regarding the localization of the pathology (Table 8.1). Sensory syndromes that relate to injury at different levels of the neuraxis are discussed in the following section, which also discusses the main sensory pathways of the nervous system.

Central Sensory Syndromes

Cortex

Numbness and paresthesias can result from both lesions in the central or peripheral nervous system. Higher cortical sensory functions are localized to the parietal cortex, with the primary

FIGURE 8.1 Sites of origin of pain within the nociceptive pathway. NSAIDs, nonsteroidal anti-inflammatory drugs. (Adapted from Marshall R, Mayer S. *On Call Neurology*. 3rd ed. Philadelphia, PA: Saunders; 2007.)

TABLE 8.1 Patterns of Sensory Loss

Localization	Sensory Pattern	Associated Findings
Cortical	• Contralateral sensory loss	• Cortical sensory loss (ie, neglect, astereognosis, agraphesthesia) • Visuospatial deficits
Brain stem	• Contralateral sensory loss of arm and leg with ipsilateral loss in face	• Cranial neuropathies (ie, ophthalmoparesis, facial weakness) • Ataxia • Contralateral weakness • Hyperreflexia
Spinal cord	• Complete transverse lesion: loss of all sensory modalities below the level of the lesion • Central cord lesion (ie, syrinx): loss of pain and temperature at and/or below the level of the lesion • Anterior cord lesion: contralateral loss of pain and temperature sensation below level of the lesion • Cord hemisection (Brown-Séquard syndrome): ipsilateral loss of vibration and joint position below the level of the lesion and contralateral loss of pain and temperature two or three segments below the level of the lesion • Cauda equina syndrome or conus medullaris syndrome: saddle anesthesia	• Contralateral or complete paralysis below the level of the lesion • Change in bladder or bowel control • Areflexia/hyporeflexia at the level of the lesion with hyperreflexia below the lesion • Dissociation between sensory modalities
Brachial plexus	• Ipsilateral sensory loss in the distribution of more than one peripheral nerve or nerve root	• Weakness in the distribution of the involved peripheral nerves or nerve roots • Areflexia • Neuropathic pain
Dorsal root ganglion	• Complete loss of sensation of all modalities in the affected dermatome	• Neuropathic pain • No weakness
Nerve root	• Loss or diminution of all sensory modalities in the affected dermatome	• Radicular pain • Weakness in the corresponding myotome • Areflexia or hyporeflexia
Peripheral nerve (also see Fig. 8.1)	• Mononeuropathy: loss or diminution of all sensory modalities in the distribution of the nerve • Polyneuropathy: distal and symmetric loss of sensation (vibration and joint position in cases of large-fiber neuropathy and pain and temperature in cases of small-fiber neuropathy) • Mononeuritis multiplex: loss of sensation in various peripheral nerves in an asymmetric fashion	• Weakness involving muscles of the corresponding peripheral nerve • Distal and symmetric weakness in cases of large fiber polyneuropathy • Autonomic findings • Neuropathic pain • Areflexia or hyporeflexia

sensory cortex being the postcentral gyrus of the parietal lobe. Lesions of the parietal lobe such as tumors or vascular insults (ie, stroke, vascular malformation, hemorrhage) may cause sensory loss and numbness and are often associated with other impaired parietal lobe functions clinically manifested by poor visuospatial skills and hemineglect. Subcortical lesions in the parietal lobe may also manifest with loss of sensation as can be seen with demyelinating plaques of multiple sclerosis. Migraine (see Chapter 56) is a condition of the central nervous system that can often be associated with sensory phenomenon both of the face and extremities, either as a migraine "aura" or associated with the pain itself. Further questioning regarding associated factors and timing will help direct one toward a differential diagnosis as discussed below.

Brain Stem

Brain stem lesions involving the trigeminal nucleus, medial lemniscus, or spinothalamic tract may also present with unilateral facial or limb numbness but are typically associated with other brain stem findings such as ophthalmoparesis, weakness, or ataxia.

Spinal Cord

Numbness resulting from spinal cord injury may correspond to a particular dermatome but may also lead to a sensory level, in which the entire body below the lesion is affected (see Chapter 17). Examples of this include cases of transverse myelitis, in which patients may present with a sensory level with complaints of numbness extending down from a particular dermatomal level. The two main central sensory pathways in the spinal cord are the *dorsal columns*, also known as the *medial lemniscus*, and the *spinothalamic tract*. Neurons carrying information related to vibration sense and proprioception travel up the cuneate and gracile fasciculus (which form the dorsal columns) in the spinal cord and synapse in their respective nuclei in the medulla, after which they decussate and form the medial lemniscus which carries these fibers to the ventral posterolateral nucleus of the thalamus before terminating in the postcentral gyrus of the parietal lobe.

Fibers carrying pain and temperature sensation form the lateral spinothalamic tract in the spinal cord and typically ascend two spinal levels in Lissauer tract in the ipsilateral cord before synapsing with a second-order sensory neuron. From there, they decussate in the anterior white commissure to the contralateral cord, and the tract then travels up the remainder of the spinal cord and brain stem and synapses again in the thalamus. Pathology of the posterior limb of the internal capsule or ventral posterolateral nucleus of the thalamus may also cause numbness, and sudden-onset isolated numbness of a limb in a patient with vascular risk factors should raise concern for a possible vascular event in these regions. Similarly, sudden-onset numbness of the face may result from a lesion in the ventral posteromedial nucleus of the thalamus.

Numbness resulting from spinal cord injury may also be accompanied by weakness and changes in bowel or bladder function. Depending on which segment of the cord is injured, patients may have preferential involvement of one tract or another and may have only certain sensory modalities affected; one classic example of this is the *Brown-Séquard syndrome*, where a spinal cord hemisection leads to ipsilateral weakness and loss of vibration and joint position sense below the level of the lesion and contralateral loss of cold and temperature sensation two or three segments below the level of the lesion (see Fig. 8.1).

Peripheral Sensory Syndromes

Nerve Roots and Dorsal Root Ganglia

Injury to the dorsal nerve root just distal to the spinal cord may cause numbness and pain in the setting of a *radiculopathy*—a patient may complain of radiating pain of an electric quality, at times associated with muscle soreness in that region. Sensory loss in a specific dermatomal distribution may be seen on exam (see Fig. 4.12), and depending on the severity of injury, there could be weakness in muscles of the corresponding myotome. The dorsal root ganglion is a group of nerve cell bodies (of first-order sensory neurons that are pseudounipolar) distal to the spinal cord carrying somatic afferents to the cord. A *sensory ganglionopathy* refers to the selective destruction or involvement of the dorsal root ganglion and clinically typically manifests as a sensory ataxia with profound deficits in proprioception, at times also with marked neuropathic pain and paresthesias. A ganglionopathy of this type may be autoimmune, paraneoplastic (specifically related to anti-Hu antibodies), toxic, or associated with a paraproteinemia or with Sjögren syndrome.

Plexuses

Processes affecting the brachial or lumbosacral plexus often present with pain as well as numbness and weakness in one limb in the distribution of more than one peripheral nerve or nerve root that tends to be more subacute in onset. *Brachial plexopathy* is the most common of these and can result from trauma, tumor infiltration, or a postinfectious autoimmune process or can often be idiopathic. Radiation resulting from treatment of certain cancers can also predispose to plexopathies in situations where the radiation is in close proximity to the plexus (ie, lumbosacral plexopathy seen after radiation for prostate cancer).

Peripheral Nerves

Neuropathic pain and numbness is a classic complaint in diseases of the peripheral nerves, such as in *polyneuropathy* (see Chapter 91). These patients will often complain of numbness and neuropathic pain that is distal and symmetric, typically starting in the feet. Polyneuropathy may preferentially affect large myelinated nerve fibers (group A fibers) carrying information related to vibration and joint position sense or small unmyelinated nerve fibers (group C fibers) transmitting pain and temperature sensation (see Fig. 8.1). Polyneuropathy can be either primarily axonal (with a predominant loss of axonal integrity) or demyelinating (due to destruction of the myelin sheath and often autoimmune in origin). Peripheral nerves may also be injured or damaged in isolation (ie, mononeuropathy as seen with carpal tunnel syndrome with medial nerve involvement) or together in cases of *mononeuritis multiplex*, classically a painful condition seen in cases of vasculitis where different peripheral nerves are affected in rapid succession. Diseases of the neuromuscular junction and muscle do not present with sensory complaints, although some patients may complain of proximal muscle pain (as with the inflammatory myopathies).

FOCUSED HISTORY

A detailed history is the best tool a clinician has in the initial evaluation of a patient with sensory complaints. First, one must try to characterize the nature of the complaint. It is helpful to determine the nature of the pain or numbness and whether the patient is referring to a complete lack of sensation or the presence of an abnormal sensation (ie, paresthesias). One must inquire as to the timing of symptom onset, because an acute or sudden onset of numbness may point more toward a vascular lesion (ie, stroke) than toward a progressive process and may require more urgent evaluation. *Red flags suggesting a more serious structural problem in a patient with primary sensory complaints include the presence of fever, muscle weakness, and bowel or bladder changes.*

Numbness and Paresthesias

When evaluating complaints of numbness or paresthesias, the *anatomic distribution* is important to determine, as this will help with localization and differential diagnosis: For instance, numbness or paresthesias localized to a specific dermatome will have different implications than numbness involving an entire limb. Sensory loss slowly progressing over both arms and sparing the legs may suggest an expanding cervical spine mass or a syrinx. One must ask about symmetry, duration of symptoms, and any alleviating or exacerbating factors. For instance, neuropathic pain due to polyneuropathy often worsens at night while patients are in bed, and radicular pain/paresthesias may be elicited with specific movements of the neck or back. In order to help formulate a differential diagnosis, it is crucial to ask about various *associated symptoms*. Numbness associated with changes in bowel or bladder habits may point toward a spinal cord lesion. Asking about any *precipitating events* such as trauma, positional changes, or a recent illness is also crucial. A recent history of viral infection associated with quickly ascending numbness should alert one to the possibility of Guillain-Barré syndrome. Asking about any recent trauma or injury may also help differentiate between an acute as opposed to a chronic nerve injury. Questions regarding gait are pertinent, as patients with polyneuropathy may complain of imbalance early in the disease course. The progression of symptoms is also of importance, as sensory symptoms moving in quick progression over a contiguous area may either be suggestive of a migrainous phenomenon or of the Jacksonian march of a partial seizure.

Pain

Acute pain is often managed very differently from chronic pain, as the former may respond well to a brief course of a particular kind of analgesic, whereas the latter may require a complex regimen of medications. *Back pain* (see Chapter 113) is one of the most common complaints in neurology, and one must differentiate between benign causes of low back pain and other more concerning causes, which may be indicative of a more serious diagnosis. An acute disk herniation is characterized by an abrupt onset often incited by lifting, Valsalva maneuver, or a sudden positional change. Lying down typically relieves this pain, whereas it is exacerbated by movement. It may be associated with radicular pain in the distribution of a particular dermatome. Chronic back pain is often challenging to treat and may require a complex therapeutic approach including medications, physical therapy, pain management, and sometimes surgical intervention.

Past Medical History

The patient's past medical history is important as well, as certain systemic illnesses may point toward an underlying etiology of the patient's symptoms. For instance, there are several conditions that may be associated with peripheral neuropathy, such as diabetes mellitus, rheumatologic diseases, or a history of cancer. A prior history of stroke of the thalamus or lateral medulla may contribute to a chronic pain syndrome (*Dejerine-Roussy syndrome*). A comprehensive list of current medications is also important to gather, as paresthesias can at times be a known side effect of certain medications (ie, paresthesias of the hands with use of topiramate). When obtaining the family history, one must be careful to inquire as to any possible neurologic diseases or any family members with a history of known neuropathy or foot deformities that may, for instance, point toward Charcot-Marie-Tooth disease. Exposure to certain substances such as heavy metals, pesticides, or chemotherapeutic agents may be implicated in those with neuropathy (some of which can be quite painful), and thus, one should ask about these possibilities when no other clear etiology can be found.

FOCUSED EXAM

The examination of a patient complaining of numbness is often challenging, as the sensory exam is the most subjective part of the neurologic exam. See Chapter 4 for a complete description of the neurologic exam.

General Medical Examination

As with all other patients, one should begin with a thorough general medical examination to look for any hints of a possible systemic disease or other findings that may be associated with the patient's complaints. For a patient with numbness or neuropathic pain, this should include an examination of the skin, assessing for rashes, hair loss, or trophic skin changes as can be seen in patients with neuropathy. Although often difficult, looking directly at the skin of the affected region may be very telling—for instance, in a patient with neuropathic pain confined to a particular dermatome, patchy erythema with grouped vesicles may be diagnostic of herpes zoster (although zoster may present without a rash, as in zoster sine herpete, or the rash may present after the onset of pain). Any patient with acute onset of numbness in which a vascular event is suspected should have a thorough cardiac evaluation and examination of the carotid arteries.

Examination of the extremities should also involve an assessment of both active and passive range of motion of affected limbs, including a *straight-leg raise test* (when indicated), which may be positive in cases of lumbosacral radiculopathy (see Fig. 4.18). A straight-leg raise is performed while having the patient lie supine as the examiner raises each leg up vertically. If the test is positive, the patient's radicular symptoms are reproduced with passive lifting of the leg (particularly the contralateral leg), as the nerve roots are stretched. *Spurling sign* is positive for cervical radiculopathy when the pain is reproduced by passively extending the neck, laterally flexing the neck toward the symptomatic side, and applying axial loading to the top of the head. *Lhermitte sign* can at times be elicited with passive flexion of the neck and is positive when the patient reports a feeling of paresthesias radiating down the arms or legs. This is caused by pressure over the posterior columns and

suggests a lesion in the posterior cervical cord as can be seen in patients with multiple sclerosis. *Tinel* and *Phalen* signs can elicit signs of median nerve compression from carpal tunnel syndrome in patients with unilateral or bilateral hand numbness (see Fig. 4.17).

Neurologic Examination

Mental Status

The majority of patients with complaints of paresthesias or neuropathic pain should have an entirely normal mental status. An abnormal finding in the patient's mental status examination points toward a cortical lesion. Higher cortical sensory function can be assessed by testing for *graphesthesia* (the ability to identify a number or letter written on the skin) and *stereognosis* (the ability to recognize an object placed in one's hand without visual or auditory stimuli). Testing for hemispatial neglect or extinction may also help identify a parietal lobe lesion.

Cranial Nerves

Similarly, a comprehensive examination of the cranial nerves can help to further localize a brain stem problem. A cranial neuropathy of any kind also suggests a central lesion as can be seen with a brain stem process or an intracranial lesion. Facial pain and neuropathies of the trigeminal nerve are discussed in detail in Chapters 57 and 89.

Motor Examination

A thorough motor examination is crucial to the evaluation of a patient with numbness and pain. In cases of chronic peripheral nerve injury, one may see atrophy of muscles in the distribution of the affected nerve. When pain is severe, a reliable determination of strength is often difficult to make. Similarly, when numbness is profound (particularly when proprioception is markedly affected), one may mistake joint position impairment for weakness. Weakness in the same distribution as numbness may point to a central lesion in the brain or spinal cord or a peripheral process in the nerve root or peripheral nerve. Distal and symmetric weakness is often most suggestive of a large-fiber polyneuropathy. Ataxia noted on finger-to-nose tests or heel-knee-shin tests may help localize a lesion to the brain stem; however, one may also find a marked sensory ataxia on coordination testing if joint position is markedly impaired.

Sensory Examination

The sensory examination is the most subjective part of the neurologic examination and often the most challenging. Several modalities can be tested and which ones are tested and how is dictated by the clinical presentation. Paresthesias that are transient and sporadic are infrequently associated with a clear loss of sensation on exam.

When examining sensation, it is helpful to keep in mind *three basic principles* (Table 8.2). Taking the time to map out a specific distribution of numbness is often diagnostic and of localizing value. For instance, in suspected spinal cord lesions, one should assess for a sensory level, which may suggest the location of the cord pathology. One can begin with an assessment of light touch sensation, for example, using the tip of a cotton swab. Pinprick sensation and temperature sensation evaluate the integrity of the spinothalamic tract and small unmyelinated nerve fibers, whereas a selective loss of vibration or joint position implies injury to the posterior columns or to the large myelinated nerve fibers as seen in polyneuropathy.

TABLE 8.2 Basic Principles of Sensory Examination

- Is the sensory loss symmetric?
- Does it follow a distal pattern?
- Does it correspond to a particular territory (ie, of one dermatome or one peripheral nerve)?

Vibration sense is determined using a 128-Hz tuning fork placed over a bony prominence, most commonly the big toe and medial malleolus of the ankle (see Fig. 4.13). Once the vibrating tuning fork is placed over the joint, one can begin to count until the patient reports no longer feeling the sensation. Alternatively, once the patient reports he or she no longer feels the vibration, the tuning fork can be placed over the examiner's metacarpophalangeal joint. Interpretation of the vibratory exam must take into account the patient's age, as vibration sense diminishes with age over time and can be absent in those older than 80 years old. Joint position is tested by moving the most distal joint passively up or down and asking the patient the direction of movement. Typically, the most subtle of movements should be detected, and if a problem is found in the most distal joint, one should move more proximally to determine the full extent of impairment. In those with severe joint position sense abnormalities, involuntary movements of the fingers may be observed with arms outstretched (*pseudoathetosis*).

Reflexes

Deep tendon reflexes are important to elicit, as they may be pathologically brisk or hyperreflexic in cases of central lesions—for instance, in spinal cord injury, reflexes may be diminished or absent at the level of the lesion but increased below the level of the lesion. In cases of peripheral neuropathies, reflexes are typically diminished or absent.

Gait and Station

A careful assessment of gait, including stance, toe walking, heel walking, and tandem gait, is also of importance, for example, as loss of balance is often a key complaint in cases of polyneuropathy. A positive Romberg test suggests impaired proprioception as can be seen with disorders of the posterior columns or with advanced large-fiber polyneuropathy.

DIAGNOSTIC EVALUATION

Following a comprehensive history and exam, one should consider appropriate diagnostic studies based on the differential diagnosis and most likely localization. Remember that when the pattern of sensory loss and history does not fit any particular diagnostic entity and the examination is entirely normal, one should consider a physical manifestation of an underlying psychiatric condition after ruling out any treatable causes.

Serologic Tests

Various tests are available to us in working up patients with neuropathic pain and numbness. Serum studies are routinely done early on in the workup and in cases of sensory loss should include electrolyte and vitamin levels (particularly vitamins B_{12}, B_6, B_1) as well as a hemoglobin A_{1c} level, as vitamin deficiencies

and diabetes are common systemic illness that often contribute to nerve damage. Depending on the clinical scenario and index of suspicion, serum testing can be expanded to include testing for human immunodeficiency virus, Lyme disease, thyroid function, hematologic malignancies, rheumatologic diseases, and various other illnesses. In any patient presentation suggestive of a peripheral polyneuropathy, a serum protein electrophoresis with immunofixation should be done to assess for a monoclonal protein. In those patients with a history of specific environmental exposures, testing can be done to evaluate for the presence of specific toxic agents such as heavy metals. Genetic causes of numbness and paresthesias exist (ie, Charcot-Marie-Tooth disease, hereditary neuropathy with liability to pressure palsies), and genetic testing should be pursued in those with a family history and the appropriate clinical phenotype.

Neuroimaging

If a central lesion is suspected, imaging studies are typically done early to evaluate for a structural lesion. Magnetic resonance imaging (MRI) (see Chapter 22) has the highest sensitivity and is the preferred imaging modality; however, a computed tomography scan can be done in patients unable to tolerate or undergo MRI testing. Spine imaging in particular can be instructive when considering a lesion at the level of the cord or the nerve root. In those patients in whom MRI is not feasible, computed tomography myelography can be used to assess for structural lesions of the spine and nerve roots. More distally, imaging of the brachial plexus is at times instructive in providing a more clear etiology in cases of plexopathy and can be used to evaluate for hemorrhage, inflammation, or infiltrative lesions.

Lumbar Puncture

Lumbar puncture (see Chapter 32) should be performed in cases of suspected inflammatory, infectious, or neoplastic processes. It is particularly helpful in cases of suspected autoimmune demyelinating neuropathies, which will show a characteristic albuminocytologic dissociation with elevated protein in the setting of a normal cell count.

Electrodiagnostic and Quantitative Sensory Testing

Nerve conduction studies and electromyography are important in helping to diagnose conditions of the peripheral nervous system and can help localize a complaint of numbness or neuropathic pain to the nerve root, plexus, or peripheral nerve (see Chapter 27). These tests have long been the standard practice in the diagnosis of neuropathy involving large nerve fibers and can characterize the severity of injury as well as distinguish between generalized and focal forms of either purely axonal or demyelinating forms of neuropathy (such as acute or chronic inflammatory demyelinating neuropathy). Nerve conduction study techniques are not sensitive in the assessment of small nerve fibers and are normal in cases of small-fiber neuropathy. More extensive quantitative sensory testing can be done in certain patients to more sensitively assess sensory dysfunction. Quantitative sensory testing uses noninvasive methods to determine the sensory threshold to various modalities including vibration, temperature, and pain and compare it to standardized normal values.

Skin and Nerve Biopsy

Given the inability of routine electrodiagnostic tests to assess for involvement of small unmyelinated cutaneous nerve fibers, a diagnosis of small-fiber neuropathy is typically made via *skin* biopsy which is done with two small punch biopsies of two different areas of skin (one proximal and one distal). *Nerve biopsy*, a more invasive test, is typically best reserved for cases involving large nerve fibers in which the diagnosis is in question and there is no known etiology (see Chapter 33). The diagnostic yield and use of nerve biopsy are best seen in cases of inflammatory, demyelinating, or infiltrative etiologies of neuropathy, with the most informative being those done on a nerve with abnormalities demonstrated on nerve conduction studies.

INITIAL MANAGEMENT

Identify Potentially Serious Conditions

Most patients with complaints of pain or paresthesias can be safely evaluated on an outpatient basis; however, exceptions certainly do exist. *Acute conditions that may lead to rapid deterioration must be identified promptly and treated as such.* For instance, a patient presenting with acute-onset lateralized numbness with vascular risk factors should be directed to the emergency room for stroke evaluation. Similarly, a patient with suspected Guillain-Barré syndrome or transverse myelitis should be evaluated rapidly and admitted to the hospital, as a delay in treatment could result in rapid deterioration and possible respiratory compromise. Inpatient hospitalization for treatment with steroids, intravenous immunoglobulin, plasmapheresis, or other immunomodulatory agents is at times necessary for these patients depending on the clinical situation.

Symptomatic Treatment

Once all diagnostic tests are completed, treatment of pain and paresthesias is twofold. The first approach is to treat the underlying etiology of the symptoms—for instance, if a structural lesion is found, surgical intervention may be appropriate, or if an autoimmune condition is diagnosed, treatment with immunomodulatory therapy is indicated. Patient with diabetes should be counseled regarding glycemic control and diet modification, those with vitamin deficiencies should be repleted, and so forth. Second, symptomatic therapy should be initiated to help with bothersome symptoms. *The treatment of neuropathic pain and paresthesias is vast and is discussed in detail in* Chapter 59. Symptomatic treatment should be multidisciplinary and include a combination of pharmacologic measures, physical therapy, and behavioral modifications. Chronic pain is often markedly challenging to treat and can be frustrating to both patients and practitioners alike.

Headache and Facial Pain 9

Ashhar S. Ali and Julio R. Vieira

KEY POINTS

1. The *International Classification of Headache Disorders*, 3rd edition, is used to differentiate the various types of headache disorders.
2. The "SNOOP" pneumonic is a useful tool to help distinguish between primary and secondary headache disorders.
3. Emergency department treatment of migraine should ideally consist of parenteral therapies, which allow for rapid and sustained relief and avoidance of opioids.
4. Craniofacial pain syndromes are rare, and secondary causes must be ruled out.

INTRODUCTION

Headache is one of the most frequent reasons for which patients seek medical attention and, when accounting for direct and indirect costs, accounts for more disability on a global scale than any other neurologic disorder. The appropriate management of headache disorders relies on (1) a careful diagnostic approach that is based on an understanding of the physiologic mechanisms of head pain and (2) symptom recognition of primary and secondary headache disorders.

GENERAL PRINCIPLES

A classification system for headache disorders has been established by the International Headache Society. The most recent version, *International Classification of Headache Disorders*, 3rd edition, divides headache disorders into *primary* headaches (in which the headache and associated features constitute the disorder itself) and *secondary* headaches (in which the headache is due to a serious underlying disorder).

The most common primary headache syndrome is tension headache, with a lifetime prevalence of around 70% to 90%. However, tension headache is rarely debilitating and is generally self-treated with over-the-counter medications. The second most common primary headache disorder is migraine, with a 1-year prevalence of 12% (17% among women and 6% among men, peaking around the fourth decade of life). Recurrent and disabling headaches in a primary care setting are most often migraine. Although life-threatening headache presents infrequently, caution is needed to ensure proper diagnosis and management.

DIAGNOSIS

History

The key to a proper diagnosis of headache is to obtain a comprehensive and precise history. Important components of the headache history include the following:

- **Onset**: abrupt versus insidious; age of onset; context in which headache began (eg, recent head or neck trauma including head/neck surgeries, systemic illness, pregnancy/postpartum)
- **Timing**: chronicity, duration, and frequency of headache attacks; time to maximal intensity; diurnal versus nocturnal
- **Quality**: sharp, dull, pressure-like, throbbing, aching, stabbing, lancinating, burning
- **Laterality**: unilateral versus bilateral; side-locked versus alternating
- **Location**: retro-orbital, frontal, temporal, occipital
- **Severity**: visual analog pain scale; disability and interference with routine activity
- **Change**: difference in pattern from prior headaches
- **Associated symptoms**: sensitivity to stimuli (eg, light, noise, smell, movement); nausea/vomiting; visual changes; numbness/tingling of the face or extremities; focal motor weakness; impairment of speech; light-headedness/vertigo; cognitive dysfunction
- **Cranial autonomic features**: lacrimation, conjunctival injection, eyelid edema, ptosis, pupillary changes; nasal congestion or rhinorrhea; aural fullness or tinnitus
- **Premonitory features**: symptoms that precede headache attacks, hours to days prior (eg, yawning, sleepiness, increased thirst, changes in bowel/bladder pattern, neck stiffness); typically a feature of migraine
- **Postdrome**: symptoms that follow headache attacks, typically lasting 1 to 2 days (eg, inability to concentrate, fatigue, mood alterations); typically a feature of migraine
- **Identifiable triggers**: menstrual cycle; skipping meals; lack of sleep or oversleeping; stress; altitude or barometric changes; positional change (lying down vs standing up); Valsalva maneuvers or physical exertion; alcohol; caffeine; cigarette smoke
- **Family history**: of primary headache disorders; cerebral aneurysm; brain tumor or malignancy

Medical and psychological history, review of systems, social history, concomitant medications, prior imaging, and laboratory testing should also be reviewed in detail, as these may suggest an underlying cause for the headache.

Physical Examination

The physical examination should include a comprehensive systemic and neurologic examination with particular attention to the following: bruits of the head or neck, temporal artery tenderness and pulsations, pericranial nerve tenderness (occipital, auriculotemporal, supraorbital, etc), pupillary size and symmetry, funduscopic examination (for evaluation of papilledema and venous pulsations), visual field testing, extraocular movements, facial sensation, cervical spine tenderness and range of motion, temporomandibular joint function, motor function, and deep tendon reflexes.

Primary Versus Secondary Headache

The first goal of diagnosis is to differentiate between a primary headache disorder, such as migraine, tension, or cluster, and a secondary headache disorder, in which headache is a symptom of an underlying illness, such as a brain tumor or malignant hypertension. There are tools available to help us distinguish between these two and are detailed in the following sections.

"Red Flags"

Symptoms that may point to a serious underlying disorder can be evaluated by the mnemonic "SNOOP" (Table 9.1). The presence of any features of SNOOP raises concern for a secondary headache and should prompt further diagnostic evaluation.

Alarming causes of secondary headache that require urgent evaluation include meningitis, intracranial hemorrhage, acute cerebral ischemia, tumor or obstructive lesion, acute angle closure glaucoma, acute sinusitis, cortical venous sinus thrombosis, cervical artery dissection, pituitary apoplexy, posterior reversible encephalopathy syndrome, and reversible cerebral vasoconstriction syndrome. Diagnostic testing, at the bare minimum, should include computed tomography (CT) or magnetic resonance imaging (MRI) of the head and selected laboratory testing. Thyroid disorders (most commonly hypothyroidism), hematologic disorders, and iatrogenic causes (such as medication side effect) may also contribute to headache in the outpatient setting and require further diagnostic evaluation.

TABLE 9.1 "Red Flags" When Evaluating Headache Symptoms[a]

Systemic	Systemic signs/symptoms: fever, night sweats, weight loss; new headache during pregnancy or postpartum; and comorbid systemic disease (eg, HIV, malignancy)
Neurologic symptoms/signs	Change in mental status; alteration of consciousness; seizure; papilledema, ataxia, focal exam findings sensation; headache induced by Valsalva maneuvers (bending, lifting, cough, sneezing)
Older	Onset after age 50 years
Onset	Abrupt, sudden, "thunderclap"
Pattern change	Change in frequency, severity, or clinical features of the attack from previous headache history; subacute worsening over days/weeks or accelerating pattern

Abbreviation: HIV, human immunodeficiency virus.
[a]Adapted from Silberstein SD, Lipton RB, Dodick D, et al. *Wolff's Headache and Other Head Pain*. 8th ed. New York, NY: Oxford University Press; 2008.

The evaluation of a patient who presents to the emergency department with a red flag is shown in Figure 9.1.

"Green Flags"

Certain clinical features support a primary headache disorder. Simple tools that can help identify migraine in a primary care setting include *ID Migraine*, a set of three questions assessing for photophobia, nausea, and disability, simplified as "PIN" (photophobia, inability to function, and nausea). If two out of the three features are present, a diagnosis of migraine is likely (with sensitivity of 84% and specificity of 76%). Another tool is the *POUND* mnemonic (Table 9.2), in which the presence of at least four out of five features can accurately predict a diagnosis of migraine.

Despite present guideline recommendations, many clinicians order testing, particularly neuroimaging, for uncomplicated primary headache disorders, such as migraine. Consequently, the American Headache Society has created the "Choosing Wisely" recommendations to address the need for neuroimaging as follows:

- Don't perform neuroimaging studies in patients with stable headaches that meet criteria for migraine.
- Don't perform CT imaging for headache when MRI is available, except in emergency settings.

PRIMARY HEADACHE DISORDERS

The primary headache disorders are discussed in Chapter 56.

SECONDARY CAUSES OF HEADACHE

Meningitis

Presence of fever, stiff neck, and Kernig and Brudzinski signs (poor sensitivity but good specificity) warrant further workup with urgent imaging (CT/MRI), followed by lumbar puncture for cerebrospinal fluid (CSF) analysis to assess for an infectious or inflammatory meningitis. If suspecting bacterial meningitis, cover with empiric antibiotics while awaiting CSF results and blood cultures.

Subarachnoid Hemorrhage and Intracranial Aneurysms

A "thunderclap headache" or "worst headache of life" can be suggestive of subarachnoid hemorrhage. Patients with this presenting symptom, which may be alongside focal neurologic symptoms or alteration in consciousness, should undergo emergent noncontrast head CT. If this is negative and subarachnoid hemorrhage is still suspected, lumbar puncture should be performed (checking for the presence of red blood cells or xanthochromia). Further workup may include an MRI of the brain and vessel imaging with either computed tomography angiogram (CTA), magnetic resonance angiogram (MRA), or a conventional angiogram.

Small unruptured intracranial aneurysms are typically asymptomatic. However, *large* unruptured intracranial aneurysms may present with focal neurologic deficits.

- A third nerve palsy suggests a possible posterior communicating artery aneurysm.
- A sixth nerve palsy can suggest a posterior fossa lesion or increased intracranial pressure.

FIGURE 9.1 Evaluation of a patient with headache in the emergency room. Abbreviations: CRP, C-reactive protein; CT, computed tomography; CTA, computed tomography angiogram; CTV, computed tomography venography; EDH, extradural hemorrhage; ESR, erythrocyte sedimentation rate; ICH, intracerebral hemorrhage; ICP, intracranial pressure; LP, lumbar puncture; MRI, magnetic resonance imaging; MRV, magnetic resonance venography; RBC, red blood cell; SAH, subarachnoid hemorrhage; SDH, subdural hemorrhage; WBC, white blood cell. (Adapted from Gordon DL. Approach to the patient with acute headache. In: Biller J, ed. *Practical Neurology*. 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2012:194-206.)

- Bilateral leg weakness or abulia may signify an anterior communicating artery aneurysm.
- Aphasia, hemiparesis, or neglect can suggest a middle cerebral artery aneurysm.

Brain Tumor

Approximately 30% of patients diagnosed with a brain tumor report headache at presentation; however, only 1% present with headache as the *only* clinical symptom. Apart from focal neurologic deficits, clues that may suggest an intracranial lesion include sudden change in pattern of a preexisting headache disorder, worsening of headache with Valsalva maneuvers and exertion, or headache that awakens one from sleep. However, these characteristics are also commonly seen in primary headache disorders, such as migraine and cluster headache. MRI brain with and without contrast can help determine the presence or absence of a neoplasm.

TABLE 9.2 POUND Mnemonic for Identifying Migraine Headache

Pulsatile quality of headache
One-day duration (4-72 h)
Unilateral location
Nausea or vomiting
Disabling intensity

Subdural Hematoma

Headache is reported in 80% of cases of subdural hematoma and is more insidious in onset than in subarachnoid hemorrhage. Characteristics may resemble those of a brain tumor (due to mass effect). Mental status changes and gait instability are common in the elderly who are at risk for acute-on-chronic subdural bleeding (often from nonwitnessed or nonreported falls). Head CT is the initial screening test of choice. Of note, a CSF leak may present as a nontraumatic subdural hematoma, as bridging veins may rupture secondary to the decrease in CSF volume.

Cervical Artery Dissection

Headache from carotid artery dissection is typically unilateral and may be associated with ipsilateral neck pain or a Horner syndrome. Headache from vertebral artery dissection is posterolateral and, when the dissection occurs or extends intracranially, may be accompanied by meningismus. Additionally, cervical

artery dissection may present as thunderclap headache. The CTA or MRA with fat-suppressed sequences can identify cervical artery dissection. Complex presentations additionally require conventional angiography.

Cerebral Venous Sinus Thrombosis

Approximately 90% of cases present with headache (most common feature but not specific) that worsens over days; other signs include seizures, altered mental status, papilledema, and focal neurologic deficits. This condition is most common among young adult women. Diagnosis is made with CT venography, which requires iodinated contrast, or magnetic resonance venogram (MRV).

Reversible Cerebral Vasoconstriction Syndrome

This condition often presents with thunderclap or recurrent thunderclap headache, resembling subarachnoid hemorrhage. The diagnosis is established by demonstrating the absence of blood in the CSF (which would instead indicate subarachnoid hemorrhage) and the presence of diffuse cerebral arterial vasospasm (typically with noninvasive vascular imaging, although conventional angiography may be required). Ischemic stroke and intracranial hemorrhage may be present. Resolution of the syndrome over a period of weeks is expected.

Giant Cell Arteritis

New-onset headache at age 50 years or older, with associated temporal artery tenderness or decreased temporal artery pulse, should raise suspicion for giant cell arteritis (temporal arteritis). Other associated symptoms include jaw claudication, unanticipated weight loss, fatigue, night sweats, and myalgias. An erythrocyte sedimentation rate and C-reactive protein should be checked in such presentations. If one or both are elevated, or if both are normal but clinical suspicion remains high, corticosteroids should be initiated and a temporal artery biopsy should be pursued. Headache typically resolves or greatly improves within 3 days of starting high-dose corticosteroids.

Spontaneous Intracranial Hypotension

Headache is commonly orthostatic in nature, occurring in the upright position and resolving or notably improving upon lying supine. A paradoxical presentation, albeit rare, is also possible, in which case, the headache worsens when supine and improves when upright. Pain may also be worsened by Valsalva maneuvers. Neck stiffness and nausea may be present.

If intracranial hypotension is suspected, an MRI brain with and without contrast should be performed, which may reveal subdural fluid collections, pachymeningeal enhancement, engorgement of venous structures, pituitary hyperemia, and/or sagging of the brain with cerebellar tonsil displacement. If there is no clear precipitating event (such as a recent lumbar puncture), spinal MRI with heavy T2 weighting or CT myelography should be considered to identify potential sites of CSF leakage. Treatment options include bed rest, intravenous fluids and caffeine, and a blood patch even if the site of leak has not been identified. If a leak site is identified, a CT-guided therapeutic blood patch is performed. Infrequently, the site of the leak may be repaired surgically.

Idiopathic Intracranial Hypertension

Idiopathic intracranial hypertension, formerly termed *pseudotumor cerebri*, is a syndrome of elevated intracranial pressure that usually occurs in obese women of child-bearing age. Headache may share features as seen with space-occupying lesions, such as worsening with Valsalva maneuvers, wakening from sleep, and/or intractable nausea or vomiting. Other symptoms include transient visual obscurations, photopsia, horizontal diplopia, and pulsatile tinnitus. Persistently raised intracranial pressure can also trigger migraine symptoms such as photophobia or phonophobia.

The most concerning abnormal finding on examination is that of papilledema on funduscopic examination as well as the absence of spontaneous venous pulsations. Other findings include a sixth nerve palsy. Certain medications may increase the risk for developing idiopathic intracranial hypertension, such as estrogen-containing oral contraceptives, excessive intake of vitamin A or retinoic acid derivatives, and lithium.

Brain MRI and MRV should be obtained if there is concern; imaging may reveal an empty sella, flattening of the posterior globes, protrusion of optic nerve heads, optic nerve sheath swelling, tortuosity of optic nerves, or transverse venous sinus stenosis. An elevated opening pressure (greater than 25 cm H_2O) on lumbar puncture and improvement in headache following removal of CSF is diagnostic. Initial treatment is with acetazolamide 250 to 500 mg twice a day, increasing as tolerated to a daily dose of 2 to 4 g LEVEL 1.[1] Topiramate is the next treatment of choice. Patients who do not respond to medical treatment, or those with progressive visual compromise, may require intracranial pressure monitoring and subsequent intervention, such as ventriculoperitoneal shunting or optic nerve sheath fenestration. Venous sinus stenting is a new technique with reported success.

EMERGENCY DEPARTMENT EVALUATION AND MANAGEMENT

Diagnostic Evaluation

Upon presentation to the emergency department, it is necessary to evaluate for the presence of red flags—if any are present, the algorithm in **Figure 9.1** should be followed for further workup. Useful laboratory testing include the following:

- Comprehensive metabolic panel
- Complete blood count
- β-Human chorionic gonadotropin (pregnancy test)
- Erythrocyte sedimentation rate and C-reactive protein (if concern for inflammatory condition, such as giant cell arteritis)

If there is concern for intracranial or subarachnoid hemorrhage, a noncontrast head CT should be obtained emergently. A follow-up brain MRI may later be obtained for further characterization. Vascular imaging (such as with MRA/CTA, MRV/CT venography, or conventional angiography) may be considered in specific circumstances as described previously. Lumbar puncture may be necessary in certain cases.

The absence of red flags, as well as the presence of green flags, suggests a primary headache disorder.

Migraine Treatment in the Emergency Department

Goals of Treatment

It is important to first establish the patient's baseline, as a treatment goal of pain freedom may be unrealistic in someone with long-standing chronic headache. Return to baseline may be a more achievable goal. In addition to pain reduction, improvement in other bothersome symptoms (eg, nausea, photophobia, phonophobia) should also be targeted.

Parenteral Therapies

The majority of patients who present with headache in the emergency department have intractable migraine. Most have already attempted oral medications, unsuccessfully, prior to their arrival. Therefore, parenteral therapies are more likely to yield improvement.

The initial treatment regimen should consistent of intravenous fluids, even in the absence of vomiting or clinical signs of dehydration. Additionally, dopamine receptor antagonists, such as prochlorperazine 10 to 25 mg and metoclopramide 5 to 10 mg, have both antiemetic and antinociceptive properties and can be quite effective LEVEL 1.[2-5] Patients should be monitored for the development of akathisia or other extrapyramidal symptoms. Pretreatment with intravenous diphenhydramine 25 to 50 mg can help prevent these side effects. Intravenous ketorolac 30 to 60 mg should also be considered, as long as there is no history of occlusive vascular disease or kidney impairment. Intravenous magnesium may also be effective and can be administered at doses of 500 mg to 1 g. Resultant hypotension can be avoided by first administering intravenous fluids.

Intravenous valproic acid 10 to 15 mg/kg may also be considered for treatment of intractable migraine. Use of valproic acid should be avoided in pregnant women and cautiously used in women of childbearing age as well as those with liver disease or urea cycle disorders.

Headache recurrence after emergency department discharge is remarkably frequent, occurring in approximately 75% of patients within 48 hours of discharge; thus, a discharge plan is advisable as well as close outpatient follow-up. The addition of intravenous corticosteroids, such as dexamethasone 4 to 10 mg, has been shown to decrease migraine recurrence when administered in the emergency department LEVEL 1.[2,6] A tapering dose of corticosteroids may also be given at discharge.

The schematic in **Figure 9.2** is a suggested general approach to the management of the migraine patient presenting to the emergency department. However, treatment ultimately should be tailored to the patient's individual headache characteristics, associated features, and medical comorbidities.

Inpatient Admission

Patients who do not respond to repeated cycles (at least three) of the earlier often require inpatient admission. The treatment of choice for status migrainosus is intravenous dihydroergotamine. Repetitive dosing every 8 hours, or a continuous infusion, over a 3- to 5-day course, is typically effective. Contraindications include pregnancy, uncontrolled hypertension, history of occlusive vascular disease, and use of any triptan or ergot in the preceding 24 hours. Intravenous lidocaine infusion may also be considered. This will require close cardiac monitoring. Finally, occipital nerve block may provide immediate relief from migraine and should also be considered in the inpatient setting.

Opioids

Despite evidence against the effectiveness of opioids as a migraine treatment, its administration in the emergency department remains common. Conversely, effective parenteral therapies are often underused. Opioids are not as effective for acute migraine treatment as dopamine antagonists, ketorolac, and dihydroergotamine. In addition, opioids may decrease the effectiveness of migraine-specific abortive therapies (such as triptans), increase migraine relapse with recurrent emergency department visits, and may precipitate medication overuse headache with as little as one to two doses per week.

Treatment of Other Primary Headache Disorders

Apart from migraine, patients may present to the emergency department with one of the trigeminal autonomic cephalalgias, which are covered in detail in Chapter 57. The acute treatment of cluster headache includes 100% oxygen inhaled via a nonrebreather mask at a rate of 10 to 12 L per minute for 15 to 20 minutes and/or subcutaneous sumatriptan or intranasal zolmitriptan LEVEL 1.[7,8] Alternative options include dihydroergotamine 1 mg administered intramuscularly. External vagal nerve stimulation is now also a U.S. Food and Drug Administration–approved treatment LEVEL 1.[9,10]

Paroxysmal hemicrania and hemicrania continua respond exquisitely to oral indomethacin, which can be started at a dose of 25 mg 3 times daily and gradually titrated, as tolerated, to a maximum dose of 75 mg 3 times daily.

The SUNCT (short-lasting unilateral neuralgiform headache attacks with conjunctival tearing and injection) or SUNA (short-lasting unilateral neuralgiform headache attacks with cranial autonomic symptoms) that is not responsive to oral therapies (such as lamotrigine) may require a short course of intravenous lidocaine, 1 to 4 mg/min with close cardiac monitoring.

CRANIOFACIAL PAIN

The diagnosis and management of patients with craniofacial pain can be quite challenging. Presentations can vary drastically, leading to delayed diagnosis and treatment. Most patients who present with craniofacial pain will require imaging of the head and/or neck and possibly otolaryngology referral if a secondary cause is suspected.

Neuralgic Pain

Commonly, craniofacial pain presents as *neuralgias*, which are paroxysmal, fleeting, often electric shock–like painful sensations in the distribution of a particular nerve. One cause is the presence of ectatic vascular loops that compress the associated nerve (eg, trigeminal or glossopharyngeal) at the nerve root entry zone. Demyelinating lesions at the central portions of the nerve root entry zones are also causative and are more commonly seen in younger patients who are less likely to have ectatic vascular loops. Still, other causes include nerve entrapment, as is the postulated mechanism of occipital neuralgia.

Triggers

Trigger maneuvers characteristically provoke paroxysms of pain. For instance, activation by light touch over the skin of

FIGURE 9.2 Treatment algorithm for the migraine patient in the emergency room. Abbreviations: DHE, dihydroergotamine; IM, intramuscular; IV, intravenous; SC, subcutaneous.

the affected trigeminal region (termed *trigger zone*) suggests trigeminal neuralgia. Pain with chewing hints toward temporomandibular joint dysfunction or giant cell arteritis (a jaw claudication), whereas swallowing is a trigger for glossopharyngeal neuralgia.

Dental Pain

Craniofacial pain may also be due to dental pathology or gingival irritation; provocation by hot or cold foods is typical. External stimuli, such as application of cold, repeatedly induce pain without a refractory period. Although neuralgic pain may also be triggered by external stimuli, a refractory period is usually present. This difference can be elicited by history and should not be missed.

Atypical Facial Pain

As with other painful conditions, some patients with craniofacial pain describe imprecise symptoms that do not conform to a stereotypic syndrome. In such cases, secondary causes should be ruled out via appropriate testing. Vague, poorly localized, continuous facial pain can be seen in secondary conditions such as nasopharyngeal carcinoma and other somatic diseases. In these cases, a burning, painful element often supervenes as deafferentation occurs, and evidence of cranial neuropathy appears. In many cases, however, a secondary etiology is not uncovered, and patients are ultimately given a diagnosis of "atypical facial pain." These patients should be followed up periodically as certain clues may arise through history and examination.

FACIAL PAIN SYNDROMES AND THE CRANIAL NEURALGIAS

Facial pain syndromes and the cranial neuralgias are further covered in Chapter 57.

Visual Disturbances 10

Heather E. Moss

KEY POINTS

1. Patient history is critical for differentiating ophthalmic, neurologic afferent, and neurologic efferent causes of visual symptoms.
2. Patient examination guides further localization of visual pathway disruption.
3. Ancillary structural imaging and functional testing of the visual pathway can guide diagnosis and monitoring of visual pathway disease.

INTRODUCTION

No symptom may be as disturbing or dramatic to a patient as acute vision changes. The causes span ophthalmic, neurologic, and sometimes psychiatric disease. In addition to being expert in neurologic causes, it is important for neurologists to be able to distinguish ophthalmic and psychiatric causes of visual disturbances in order to facilitate appropriate evaluation and management of the patients experiencing them.

With regard to neurologic causes of visual disturbance, they can be grouped by afferent (ie, visual perception), efferent (ie, eye movements, pupils, and eyelids), and mixed dysfunction. As with other neurologic conditions, history and physical exam findings, interpreted in the context of neuroanatomy guide localization, enable selection and interpretation of diagnostic testing and guide management.

NEUROANATOMY

Vision is perception of light. For this to occur, the eyes must be moved to and fixed on the target of interest, which is the purview of the efferent visual pathways. The light then must enter the eye, be translated into neural signals by the retina, and processed by elementary and higher level visual pathways for conscious visual perception to be experienced. Dysfunction at any point of the afferent or efferent pathways can disrupt this sensation, most commonly, and quite unhelpfully, referred to by patients as *blur*.

Afferent Visual Pathway

Light reaches the retina through the cornea, aqueous humor, lens, and vitreous before reaching the retina where it is converted to a neural signal by the photoreceptors. The cornea and lens are the optical system that focuses light on the retina. Adjustment of the native lens allows accommodation (ie, shifting depth of focus to near) (Fig. 10.1).

Neural impulses generated by the photoreceptors are processed by the intermediate retina before being transmitted to the retinal ganglion cells, which coalesce at the optic nerve head to form the optic nerve. These cells redistribute from optic nerves to optic tracts at the chiasm such that left visual fields from both eyes form the right optic tract and vice versa and extend to the lateral geniculate nucleus where they synapse. The optic radiations extend in a fan through parietal and temporal white matter to primary visual cortex in the occipital lobes, where they maintain retinotopic organization. From there, further processing occurs in the dorsal (parietal) and ventral (temporal) pathways to achieve visual spatial, movement, and recognition aspects of visual perception.

Efferent Visual Pathway

Movement of the eyes together to shift and to hold gaze is critical to the visual experience, facilitating depth perception, exploration of scenes, tracking of moving objects, and compensating for head movement. Eye movement control has both cortical and subcortical inputs with reflex control through the vestibular system and superior colliculus. Motor control is transmitted via cranial nerves III, IV, and VI to move the six extraocular muscles of each eye (Fig. 10.2).

Pupil and Eyelid Anatomy

Although often grouped with the efferent visual pathway, perhaps because of their relevance to localization, abnormalities of pupils and eyelids are more likely to impact afferent visual function. Reflex pupil diameter adjustment is important to control the amount of light entering the eye and helps to focus entering light during accommodation. The eyelid acts to clean and moisten the cornea. Dysfunction can block vision both directly and indirectly through corneal dryness.

FIGURE 10.1 Major neurologic structures in the afferent visual pathway. (Adapted from Marshall R, Mayer S. *On Call Neurology*. 3rd ed. Philadelphia, PA: Saunders; 2007.)

FIGURE 10.2 Innervation of major structures in the efferent visual pathway by cranial nerves III, IV, and VI.

Pupil dilation is controlled by the sympathetic system, which also controls Müller muscle, a small muscle that opens the upper and lower eyelids. Sympathetic dysfunction causes Horner syndrome with meiosis and slight upper (and often lower) lid ptosis. Pupil constriction is controlled by the parasympathetic system, which travels with cranial nerve III.

In addition to sympathetic control, eyelid position and function is governed by the orbicularis oculi, which acts to close the eye (cranial nerve VII), and the levator palpebrae, which acts to open the eye (cranial nerve III).

VISUAL SYMPTOM HISTORY

A careful history is helpful to localize visual disturbances to the part of the visual pathway they originate from (afferent/efferent) and where in this pathway (Table 10.1). Associated symptoms further guide localization. Tempo is helpful to triage between potential causes and urgency. The history is particularly important for transient symptoms, for which there may be no localizing findings on examination. The following are important clarifying points in the history.

Defining Severity of Symptoms

Blur can range from images not being sharp to inability to make out any details. Clarifying with the patient can be done by asking what they can't see or do helps to place their symptoms on this continuum. Asking about specific tasks such as reading at near, seeing at distance, and navigating can also be informative and suggest whether the problem is central or peripheral vision.

Defining Type of Symptoms

As with many neurologic symptoms, visual disturbances can be positive (simple to complex hallucinations) and/or negative (vision loss). Distorted images can occur due to optical disturbance in the light reaching the retina or from visual processing disturbance. Multiple images can occur due to optical disturbance in the eye, ocular misalignment, or a cerebral processing disturbance (palinopsia). Oscillopsia is shaking images either due to extra eye movements or inappropriate reflexive movements in response to head movement.

Defining How the Eyes Work Together

Critical to interpreting any visual symptom is understanding if it occurs only with both eyes open versus with one or both eyes individually. Symptoms due to the eyes not working together (eg, misalignment) only occur when both eyes are open. In these cases, covering either eye will eliminate the image from one eye and the symptoms due to the eyes not working together. Any symptom that persists with right and/or left eye only viewing is attributable to that eye or to the brain.

Remainder of History

The nature of symptoms, including when they occur (near vs far focus, different directions, different activities), associated symptoms in addition to the rest of the patient history, provides additional context for localization of the patient's symptom.

VISUAL PATHWAY EXAMINATION

Beyond the basic components of the neuroophthalmic examination (Table 10.2), examination of the patient with a visual symptom should be targeted based on their history. In the absence of positive exam findings to accompany a symptom, attempting to reproduce the symptom is an important part of the exam.

Central Vision

Visual Acuity

This is the vital sign of visual complaints. Pertinent parameters are which eye is tested, with or without glasses, at which distance (near or far), and what the patient can distinguish. In the absence of a calibrated chart, any visual stimulus can be used.

TABLE 10.1 Signs and Symptoms That Suggest Location in the Visual Pathway

Location of Lesion Along Visual Pathway	Signs and Symptoms
Anterior segment of the eye	• Blurred vision • Glare or halos • Foreign body sense in eye • Correction with squinting, pinhole, or glasses • Response to blinking • Visible opacities on exam
Retina	• Distortion (metamorphopsia) • Regional flashes of light in one eye • Circumscribed vision loss in one eye • Prolonged recovery from light exposure • Floaters • Night blindness • Purple, yellow, or green vision • Visible abnormality on retina exam
Optic nerve	• Regional vision loss in one eye • Decreased brightness • Decreased color saturation • Relative afferent pupillary defect • Optic nerve head abnormality on exam (cupping, pallor, or swelling)
Chiasm	• Bitemporal hemianopia • Pallor of both optic discs
Optic tract	• Homonymous hemianopia • Optic atrophy • Relative afferent pupillary defect in contralateral eye
Lateral geniculate nucleus (thalamus)	• Incongruent partial homonymous hemianopia or full homonymous hemianopia • Optic atrophy
Optic radiations	• Homonymous hemianopia • "Pie-in-the-sky" hemianopia, temporal lobe • "Pie-on-the-floor" hemianopia, parietal lobe • Optokinetic defect ipsilateral to parietal lobe lesion • Hemiparesis, aphasia, alexia, agnosia, somatosensory disturbance
Occipital lobe	• Homonymous quadrantanopia or hemianopia • Sparing central vision • Central hemianopia (scotomatous) • Preserved temporal crescent of hemianopic visual field
Oculomotor/vestibular system	• Oscillopsia • Diplopia

If large text can't be discerned, ability to count fingers, identify hand motion, or see light should be determined. If visual acuity is reduced, then testing should be repeated with pinhole to exclude an anterior ophthalmic problem as the cause. Visual acuity that is dramatically different between the two eyes suggests a problem anterior to the chiasm.

Color

Comprehensive tests of color vision are often not readily available in the clinical setting. Some information can be gained by asking the patient to compare perception of a red object between the two eyes. Difference between the eyes is a positive finding, more common in optic nerve than retinal disease. Ishihara or Hardy-Rand-Rittler color plates can be administered if available.

TABLE 10.2 Components of Neuroophthalmologic Examination

	Basic Exam	Advanced Exam
Central vision	• Visual acuity chart, corrected with glasses or pinhole	• Amsler grid to detect metamorphopsia (distortion of straight lines), which suggests retinal disease • Look for asymmetry in color perception or color desaturation (red). • Formal color testing • Electrophysiology testing
Peripheral vision	• Confrontation visual fields performed for each eye separately	• Formal perimetry such as Humphrey Visual Field testing • Electrophysiology testing
Pupils	• Record size in dark and in light. • Record response to light. • Perform swinging flashlight test to look for relative afferent pupillary defect.	• Response to near if no response to light • Dilation lag (Horner syndrome)
External exam	• Look for ptosis and proptosis. • Look for injection of conjunctiva.	• Measure eye position in orbit with Hertel exophthalmometer
Motility	• Look for restrictions in extraocular movement. • Characterize ocular misalignment.	• Measure ocular misalignment in different directions of gaze. • Characterize saccades, pursuit, nystagmus, optokinetic nystagmus
Funduscopic exam (ophthalmoscopy)	• Examine the fundus for optic nerve and retinal pathology.	• Dilated examination • Fundus photography • Optical coherence tomography imaging

Visual Distortion

The Amsler grid is a standardized grid of black lines on a white background that is useful for characterizing changes in central and near peripheral vision. The patient is asked to point out any missing or distorted lines when viewing the grid with each eye separately.

Peripheral Vision

This is the cardinal examination finding that guides neurologic localization of afferent pathway vision loss (Fig. 10.3). Single eye loss localizes anterior to the optic chiasm, bitemporal visual field loss (ie, outer field of each eye) localizes to the chiasm, and homonymous defects (ie, same field both eyes) localize to the visual pathways behind the chiasm.

FIGURE 10.3 Visual field cuts produced by lesions at different points along the visual pathway. (*a*) Monocular blindness produced by a lesion in the left optic nerve. (*b*) Bitemporal hemianopia produced by a mass lesion at the optic chiasm. (*c*) Right segment anopia produced by a lesion in the lateral geniculate body of the left thalamus (posterior choroidal artery stroke). (*d*) Right upper quadrantanopia produced by a lesion in the left temporal optic radiation (Meyer loop). (*e*) Right lower quadrantanopia produced by a lesion in the left parietal optic radiation. (*f*) Left homonymous hemianopia produced by a lesion in the calcarine cortex of the right occipital lobe. Note that macular vision is sometimes spared in posterior cerebral artery stroke because of middle cerebral artery collateral blood flow to the occipital pole. Abbreviation: LGN, lateral geniculate nucleus. (Adapted from Marshall R, Mayer S. *On Call Neurology*. 3rd ed. Philadelphia, PA: Saunders; 2007.)

Neither lack of positive finding on bedside visual field assessment nor lack of peripheral vision complaint excludes visual field loss due to poor sensitivity. Gold standard formal visual field testing that is used in the ophthalmology clinic is more sensitive and should be pursued if diagnosis is elusive or monitoring is important.

Confrontation Visual Field Testing

The patient's ability to count the number of fingers seen in each peripheral field (superior temporal, inferior temporal, superior nasal, inferior nasal) with each eye and its variations (eg, wiggling fingers) is a component of the basic neurologic exam (Fig. 10.4). It has good specificity for localization along the afferent visual pathway but poor sensitivity.

Comparative Visual Field Testing

A simplified test of visual fields that can be easily done at the bedside is to have the patient sequentially cover each eye and describe how their symptom changes. A symptom that is exclusively in one eye is characterized by resolution when the affected eye is covered and persistence when the fellow eye is covered. This localizes anterior to the chiasm in the affected eye or optic nerve. A symptom that is in both eyes is characterized by persistence when either eye is covered. This localizes either to both eyes anterior to the chiasm, to the chiasm, or behind the chiasm. A symptom that resolves when either eye is covered suggests that there is no lesion in the afferent visual pathway and that the symptom is related to ocular misalignment.

FIGURE 10.4 Visual field technique: Sit 1 to 2 m from the patient and have the patient cover one eye completely while looking at the examiner's nose. In quick succession, flash one, two, or five fingers in all four quadrants. Then switch eyes. (Adapted from Marshall R, Mayer S. *On Call Neurology*. 3rd ed. Philadelphia, PA: Saunders; 2007.)

Ophthalmic Examination

Once visual function has been established through central and peripheral vision testing, the ophthalmic examination is a unique opportunity to visualize the causative pathology. The typical neurology clinic and emergency department are not equipped to perform the full ophthalmic exam and consultation with an ophthalmologist or skilled optometrist may be necessary to fully assess the patient.

External Exam

Eyes can appear prominent due to lid retraction or proptosis and less prominent due to ptosis or enophthalmos. Measuring the width of the palpebral fissure, the excursion of the lid margin from downgaze to upgaze to detect levator weakness and assessing for lid curtain, twitch, and fatigue are helpful for differentiating neurologic causes of ptosis, with the latter two suggesting myasthenia gravis. Neurologic causes of proptosis include cavernous sinus congestion.

Anterior Exam

Some pathologies of the cornea and lens are evident on direct ophthalmoscopy as cloudiness or yellowing. If the doctor's view to the back of the eye is poor despite good technique, that is a clue that the patient's view with the eye is also poor due to poor light transmission. Detailed examination of the front of the eye is best done using a slit lamp in the ophthalmologist's or skilled optometrist's office.

Funduscopic Exam

Most important for the neurologic exam are visualization of the optic nerve and retina. This can be difficult through an undilated pupil. Performing the exam in a dim environment and having the patient focus at distance are helpful to maximize pupil size. The optic nerve should be examined for evidence of pallor, which suggests prior injury to the optic nerve as well as edema,

Normal or acute retrobulbar optic nerve injury | Optic nerve Head edema with blurred disc margins | Optic atrophy (chronic optic nerve injury) with pale optic nerve | Acute inferior branch retinal artery occlusion with retinal edema causing whitening

FIGURE 10.5 Key funduscopic examination findings in the neurological patient. Background color differences are attributable to patient and photographic technique.

which suggests acute injury. Blurring of the disc margins or obscuration of vessels where they cross the disc margin suggests optic nerve head edema. Retrobulbar optic nerve injury will not manifest any optic disc changes in the acute setting (Fig. 10.5).

Important retinal findings for the neurologic exam are hemorrhages and exudates, which can be seen as ophthalmic manifestations of diabetes and hypertension. Plaques in the retinal arterioles are signs of embolic disease.

Ocular Motility

Examine How the Eyes Move Individually and Together

The eyes should be examined together and separately for movement limitations. Testing of saccades (look at my pen—held to the side), smooth pursuits (follow my pen), and voluntary gaze (look to the right) should be performed with attention to whether each eye moves fully within the eye socket. Comparing between the eyes can be helpful to identify abnormalities in up, down, left, and right gaze and to identify subtle asymmetries such as adduction slowing in internuclear ophthalmoplegia (INO). If there are any limitations, evaluation of eye movements induced by reflex maneuvers (eg, vestibulo-ocular reflex using doll's eyes or caloric tests) can be helpful to localize any eye limitation to a supranuclear origin.

Examination of the extent of eye movements may be sufficient to characterize the eye movement disorder causing diplopia. However, it is important to recognize that full extraocular movements *do not* exclude a neurologic disorder causing diplopia.

Determine Eye Alignment

The goal is to define the relative alignment of the eyes (turned in = esotropia, turned out = exotropia, right eye higher = right hypertropia, left eye higher = left hypertropia) in each direction of gaze (straight ahead, up, down, left, right). This may be obvious based on inspection. If not, one important clue is to ask patients if they see double as you have them look in each direction of gaze. If they see two images, ask them if the images are horizontally, vertically, or obliquely oriented with respect to each other and if the images change in orientation/separation distance in different directions of gaze. If both the examiner and the patient are savvy observers, have the patient occlude one eye at a time to determine which image is coming from each eye. Due to the optics of the eye, the orientation of the images will be opposite to the orientation of the eyes—for example, if the right eye is higher than the left eye, the right eye image will be lower than the left eye image.

Other methods of eye alignment testing include examining the reflection of light in the pupils for relative displacement off of the center of the pupil (eg, if the light reflects of the inner iris of one eye, this suggests the eyes are relatively turned out). Alternately covering each eye while the patient fixates on an object is an easy bedside test. The examiner observes for the direction of the corrective eye movement as each eye recovers fixation.

Characterize Extra Eye Movements

Intrusive eye movements are those that interrupt gaze fixation and are assessed by having the patient attempt to maintain steady gaze in different directions. Nystagmus is characterized by rhythmic slow movements of the eyes, either with a corrective saccade (jerk nystagmus) or back to back slow movements (pendular nystagmus). Nystagmus is abnormal except for a few beats of extinguishing jerk nystagmus in lateral gazes. Peripheral vestibular nystagmus does not change direction, worsens with gaze in the direction of the fast phase, and worsens with removal of fixation. A subtle sign of INO is jerk nystagmus of the abducting eye, during lateral gaze. Nystagmoid movements include square wave jerks, which are small involuntary saccades with a latency between them, and opsoclonus, which are involuntary saccades without a latency between them.

Pupil Size and Function

Pupil size reflects the total amount of light being transmitted by both optic nerves and efferent pupillary function. There are two main pupil exam findings that are distinct from each other: anisocoria and afferent pupillary defect.

Comparing Pupils to Each Other

Pupil size should be measured under diffuse bright light and diffuse dim light. Normal pupillary function is indicated by equal size of the pupils regardless of the light exposure. Anisocoria in either bright or dim conditions reflects efferent pupillary dysfunction. In general, small pupils do not cause symptoms. Large pupils can cause light sensitivity and be associated with focusing difficulties at near.

A unilateral sympathetic lesion impairs pupil dilation with a resulting smaller pupil and anisocoria more pronounced in dim light. There is often associated mild ptosis and sometimes

ipsilateral anhidrosis (Horner syndrome). There are nonsympathetic causes of a miotic pupil including medications (eg, pilocarpine) and trauma. Cocaine, hydroxyamphetamine, and apraclonidine eye drops can guide localization of a small pupil.

A parasympathetic lesion impairs pupil constriction with a resulting larger pupil and anisocoria more pronounced in bright light. When associated with ptosis and ocular motility restrictions, this is concerning for cranial nerve III palsy. There are noncranial nerve III causes of a mydriatic pupil including medications (eg, atropine), trauma, and tonic pupil, caused by injury to the ciliary ganglion. Dilute pilocarpine can guide localization of a large pupil.

A large pupil that doesn't constrict to light but does constrict to a near stimulus is said to have light-near dissociation. This is a finding of pupil dysfunction from a tonic pupil or midbrain lesions.

Comparing Optic Nerves to Each Other Using the Pupil

The pupillary light reflex, which sets size of both pupils based on total light transmitted down both optic nerves, can be leveraged to compare the prechiasmatic visual pathways. The light is alternately shone in each eye, looking for constriction of the pupils when one eye is illuminated and dilation of the pupils when the other eye is illuminated. A subjective version of this test is to ask the patient if a standard light stimulus is perceived as equal in both eyes.

The eye with relative pupillary dilation during the swinging light test is said to have a relative afferent pupillary defect, suggestive of unilateral or asymmetric optic nerve disease, but also evident in severe retinal disease. Due to asymmetry in redistribution of ganglion cells at the chiasm, optic tract dysfunction is associated with a contralateral relative afferent pupillary defect.

Neurologic Exam

Attention should be paid to signs localizing to near the afferent and efferent visual pathways or suggesting neurologic syndromes that can involve vision loss. Of particular importance are the cranial nerves.

ANCILLARY OPHTHALMIC TESTING

Ancillary ophthalmic testing is widely available in eye care centers and increasingly available in neurology practices. It can be helpful to guide neurologic localization and for monitoring of neurologic disease.

Fundus Photography

Fundus photography techniques supplement the funduscopic examination by capturing a still or video image of the fundus. Technologic advances have made high-quality imaging possible through undilated pupils with minimal technical skill using desktop platforms. Portable platforms, including those using smartphones, are more finicky and require more technical expertise and practice to capture high-quality images. These are useful for documentation and comparison.

Optical Coherence Tomography

Optical coherence tomography (OCT) is a noninvasive imaging technique that uses near-infrared light to generate high-resolution, cross-sectional images of the optic nerve and retina (Fig. 10.6). It is in wide use in ophthalmology and optometry practices and many patients referred to a neurologist from these doctors may have had such imaging. Most relevant to neurologists is visualization of the optic nerve in three dimensions, which allows easy identification and comparison of optic nerve head edema. The analysis software also segments the images to measure the thickness of retinal layers corresponding to retinal ganglion axons around the optic nerve (peripapillary retinal nerve fiber layer (RNFL) thickness) and retinal ganglion cells in the macula (ganglion cell complex (GCC) thickness). Thickening of the RNFL can occur with optic nerve head edema. Thinning of the RNFL and/or GCC can occur with optic nerve atrophy. OCT is also helpful for visualization of retinal pathology and understanding of this, artifacts and automatic segmentation errors is important to fully interpret the images.

FIGURE 10.6 Optical coherence tomography findings in neurological patients.

Perimetry

Perimetry is formal assessment of peripheral vision and can be performed using a variety of devices. They share in common algorithms to map the peripheral vision in each eye individually and are often available in ophthalmology, optometry, and neuro-ophthalmology practices. Their utility lies in detecting and characterizing visual field loss that is sometimes below the level of detection on examination. It also has applications to detecting change (both progression and improvement) in vision loss not involving central vision.

Visual Electrophysiology

Visual electrophysiology can help to localize a lesion in the retina or optic nerve when no structural lesion is apparent. Visual-evoked potentials (VEP) record the occipital surface potential generated by a light stimulus in each eye and are useful for detecting decreased and slowed transmission. Full field electroretinography (ERG) is helpful for detecting abnormalities in the intermediate and outer retina and multifocal ERG is useful for detecting macular (central retinal) dysfunction. Optic nerve abnormalities can be detected on VEP as well as certain waveforms of the pattern ERG and full field ERG.

TRANSIENT VISUAL SYMPTOMS

Transient visual symptoms are the most challenging to assess because, by definition, they have resolved, and there may not be localizing findings on examination. Although much time can be spent trying to distinguish afferent from efferent and eye from brain events based on history, it is often difficult to determine conclusively. Therefore, a broad differential diagnosis must be considered with triage based can't miss diagnoses.

TABLE 10.3 Causes of Transient Unilateral or Hemifield Visual Loss

Etiology	Monocular (One Eye)	Hemianopic (One Field)	Binocular (Both Eyes)
Transient ischemic attack	x	x	
Hypotension, presyncope	x	x	x
Arterial spasm	x		
Recurrent erosions of the cornea or corneal basement membrane dystrophy	x		x
Angle closure	x		x
Optic nerve head edema	x		x
Orbital masses (causes gaze-evoked monocular visual loss)	x		
Uhthoff phenomenon	x		x
Migraine		x	
Ocular surface dryness	x		x
Seizure		x	

Transient Ischemic Attack

Transient ischemic attack (TIA) includes neurologic symptoms due to ischemia of the brain or retina or and must be included in the differential diagnosis for transient visual symptoms including monocular vision loss, homonymous visual field loss, and diplopia. In addition to common ischemic stroke causes of cardioembolic, large vessel, and small vessel, other important considerations include hypoperfusion related to vascular stenosis and vasculitis. Giant cell arteritis is of particular concern as a cause of transient visual symptoms in patients older than age 50 years especially those with systemic symptoms. Plaques in retinal vessels are clues to embolic events in the anterior circulation.

Ophthalmic Causes of Transient Visual Symptoms

Ophthalmic causes of transient visual symptoms typically affect one eye at a time, although due to their transient nature it is often difficult for patients to make this distinction. Most common is ocular surface changes, which often improve with blink or artificial tears. Retinal ischemia is emergent and addressed under TIA in the preceding text. Subacute angle closure can cause recurrent bouts of unilateral eye pain, blurry vision in that eye, and eye redness that are frequently misdiagnosed as migraine. Intraocular pressure is high during an attack, and narrowing of the angle between the iris and the cornea is evident between attacks. Arterial spasm in the ophthalmic, retinal, or choroidal circulation may result in transient monocular vision loss in otherwise healthy individuals. It is a diagnosis of exclusion based on stereotyped events and normal vascular workup.

Optic Nerve Causes of Transient Visual Symptoms

Transient ischemia of the optic nerve is included under TIA in the preceding text. Patients with optic nerve head elevation due to edema, optic nerve head drusen, or congenital malformation may experience graying out of vision associated with postural change or head movement. These are called *transient visual obscurations* and can occur even in the absence of chronic vision loss related to the elevated optic nerve. Mass lesions in the orbit can cause vision loss when eye movements either cause compression or vascular compromise to the optic nerve or retina. This is referred to as *gaze-evoked amaurosis*. Decrease in vision in one eye associated with increased body temperature is Uhthoff phenomenon and suggests demyelinating injury to the optic nerve, for example, due to past optic neuritis or optic nerve compression.

Cerebral Causes of Transient Visual Symptoms

Visual migraine aura is a stereotyped transient visual hallucination, typically with positive visual features and movement in a homonymous visual field, although patients often perceive it as being in one eye. Typically, it evolves over 20 minutes and resolves prior to a migraine headache. Epilepsy involving the visual pathways can cause stereotyped visual experiences.

Transient Diplopia

Diplopia is an all or none symptom, and thus, it is often episodic even if the lesion is persistent. In the case that it cannot be

reproduced in the office and ocular motility examination is normal, considerations include TIA, myasthenia gravis, and ocular neuromyotonia.

COMMON PATTERNS OF AFFERENT PATHWAY DISEASE

Ophthalmic

Most causes of monocular visual symptoms are due to eye disease and are readily apparent on a full ophthalmic evaluation (ie, dilated exam by an ophthalmologist). The exceptions are retrobulbar optic neuropathy and disease of the outer retinal layers, both of which can have normal slit lamp and dilated fundus examinations. Optic neuropathy is discussed in the following text. Outer retinal disease can often be visualized on OCT and can be detected using ERG.

For the neurologist, monocular diplopia is important to distinguish from binocular diplopia (ie, that resolves with covering either eye) because it is most likely due to an anterior ophthalmic cause. Central vision loss in one eye with or without distortion and without relative afferent pupillary defect suggests a retinal etiology rather than an optic nerve etiology.

Retinal arteriolar occlusion is an ophthalmic diagnosis relevant to neurology because the pathophysiology overlaps with that of ischemic stroke. It can be asymptomatic or cause partial or complete monocular vision loss depending on what arteriole is occluded.

Optic Neuropathy

The most important cause of monocular vision loss relevant to neurologists is optic neuropathy. Classically, there is either central or peripheral vision loss with associated change in color perception and relative afferent pupillary defect in unilateral cases. Bilateral optic neuropathies have less prominent relative color vision changes and relative afferent pupillary defects because these findings rely on comparison between the eyes. Optic neuropathy can also be asymptomatic, detected by optic disc swelling on clinical exam, or by ganglion cell thinning on OCT.

The differential diagnosis is broad and includes anterior (optic nerve head), intraorbital, intracanalicular, and chiasmal etiologies. Swelling of the optic nerve head identifies acute anterior optic neuropathies. Acute retrobulbar optic neuropathies may have a normal funduscopic appearance. Chronic optic neuropathies are associated with optic nerve head pallor. It takes weeks to month following retrobulbar optic nerve injury for pallor of the optic nerve head (reflecting axonal loss) to develop.

Acute Optic Neuropathies

Important considerations for monocular optic neuropathies that require rapid diagnosis or intervention include optic neuritis (particularly neuromyelitis optica spectrum, which may necessitate escalation of immunotherapy to induce remission); other inflammatory optic neuropathy (eg, sarcoidosis, which may require intravenous immunotherapy for treatment); arteritic ischemic optic neuropathy, which carries short-term risk of fellow eye involvement and stroke; acute compressive optic neuropathy (eg, pituitary apoplexy, which is associated with acute adrenal insufficiency); and fungal orbital apex syndrome.

Other optic neuropathies that present acutely include nonarteritic anterior ischemic optic neuropathy, which, by definition, has optic disc swelling in the acute phase and Leber hereditary optic neuropathy, which, although due to mitochondrial gene defect, typically presents with sequential monocular vision loss.

Progressive Optic Neuropathies

The most common optic neuropathy is glaucoma, typically managed by ophthalmologists. The most common form is primary open-angle glaucoma, which causes painless, asymmetric, bilateral, slowly progressive peripheral vision loss. It is associated with high intraocular pressure and defined by progression of optic disc cupping to accompany visual field loss.

Extrinsic lesions that compress the optic nerve are an important consideration in progressive optic neuropathies. The pattern of vision loss depends on what is compressed (optic nerve, chiasm, or tract). Common pathologies affecting the optic nerve include optic nerve sheath meningiomas, skull base meningiomas, pituitary tumors, craniopharyngiomas, and cerebral aneurysms.

Toxic or metabolic injuries to the optic nerves are typically bilateral and impact central vision. Vitamin B_{12}, folate, and copper are some of the vitamin deficiencies that can impact the optic nerves. Ethambutol, isoniazid, chloramphenicol, linezolid, and disulfiram are drugs that can cause a toxic optic neuropathy.

Dominant optic atrophy, the most common hereditary optic neuropathy, presents in childhood or adolescence with symmetric mild to moderately decreased acuity (20/25-20/200) that progresses and typically stabilizes in young adulthood.

Intrinsic optic nerve tumors include optic nerve gliomas, which are typically pilocytic astrocytomas that appear in young childhood association with neurofibromatosis type 1. They can present with bilateral visual loss, strabismus, nystagmus, optic atrophy, papilledema, hydrocephalus, and endocrine problems. Malignant optic gliomas of adulthood are rare, high-grade gliomas that progress rapidly to blindness and death.

Papilledema

Although many different acute anterior optic neuropathies can cause optic disc edema, papilledema, which is disc edema, typically bilateral, due to elevated intracranial pressure (ICP), is of particular importance because it can be a diagnostic clue to underlying secondary cause of high ICP such as brain tumor or venous sinus thrombosis. Papilledema can develop in the absence of subjective or objective vision loss and in the absence of other signs of high ICP such as headache.

In a patient that has papilledema, it is urgent to exclude secondary causes of high ICP. It is also important to characterize visual function with formal perimetry in order to identify and monitor vision loss, which can be progressive and permanent. Treatment of high ICP and, if possible, the underlying cause will reduce the risk of vision loss and possibly recover vision that has been lost.

Optic Chiasm

Pathologies impacting the optic chiasm tend to preferentially affect the crossing fibers classically causing bitemporal hemianopic

vision loss. This may not be noticed by the patient because the seeing fields in each eye complement each other. However, vision loss patterns can vary based on the anterior/posterior and lateral location of pathologies with posterior pathologies causing central visual field loss and lateral pathologies affecting one tract or optic nerve more than the other. There may be an relative afferent pupillary defect depending on the laterality of the pathology. Optic nerve pallor may develop weeks to months after axonal loss in the chiasm.

Common chiasmal pathologies are compression from pituitary tumor, meningioma, and craniopharyngioma. Gliomas can involve the chiasm as can inflammatory conditions such as optic neuritis and sarcoidosis.

Optic Tract

Lesions of the optic tract cause homonymous visual field loss in both eyes (ie, same field of both eyes) and a contralateral afferent pupillary defect. This is due to the fact that the tract contains more fibers from the contralateral than ipsilateral eye. Because the optic tract is composed of presynaptic retinal ganglion cells, chronic lesions are associated with bilateral optic nerve head pallor. Isolated visual symptoms are rare but can occur due to compression from a sellar or suprasellar process (eg, pituitary tumor or craniopharyngioma) or retinal ganglion cell pathology (eg, optic neuritis).

Lateral Geniculate Nucleus

Lesions to the lateral geniculate nucleus are associated with homonymous contralateral visual field loss in both eyes. Isolated visual symptoms are rare but can occur from either anterior circulation (anterior choroidal artery) or posterior circulation (posterior choroidal artery) strokes. Because the optic tract synapses in the geniculate body, optic atrophy may be observed several weeks after a geniculate lesion.

Optic Radiations

Dysfunction of the optic radiations is associated with visual field loss in the opposite field in both eyes (ie, homonymous hemianopias). For example, vision loss in the upper right visual field can be caused by dysfunction of the left temporal radiations (Meyer loop). Due to the distributed nature of the radiations, it is rare for injury to cause isolated visual symptoms, and it is typical to have other symptoms/signs that localize to the relevant parietal/temporal lobe. Differential diagnosis is that for parenchymal lesions of the brain including stroke, tumor, and demyelination among others.

Occipital Lobe

Similar to optic radiation dysfunction, dysfunction in an occipital lobe is associated with visual field loss in the opposite field in both eyes. Lesions to the occipital pole cause central vision loss. Posterior cerebral artery strokes typically spare the occipital poles to cause hemianopias with central (macular sparing). Unlike visual field defects localizing to the optic radiations, those from occipital lobe dysfunction are commonly isolated. The differential diagnosis is that for parenchymal lesions of the brain including stroke, tumor, and demyelination among others. Posterior cortical atrophy can cause homonymous visual field loss with only subtle findings on neuroimaging.

Midline (eg, falcine meningioma) or distributed processes (eg, reversible posterior leukoencephalopathy syndrome) can cause bilateral occipital lobe dysfunction and even blindness on a cerebral basis. In these cases, pupil reactivity is normal, and patients may be agnostic to their vision loss and confabulate (Anton syndrome).

Higher Order Visual Dysfunction

Visual processing occurring in the parietal and temporal lobes creates the visual experience. Dysfunction of these areas can lead to difficulties interpreting spatial relationships (eg, simultagnosia, palinopsia) and recognizing objects (alexia without agraphia, prosopagnosia).

COMMON PATTERNS OF EFFERENT VISUAL PATHWAY DYSFUNCTION

Disturbances of eye movement and ocular alignment result in diplopia in individuals who have good vision in both eyes and use both eyes together. This can result from ocular muscle problems, neuromuscular transmission defects, cranial neuropathies, and brainstem parenchymal lesions to cause double vision, which the patient may report as blurry vision. Damage to the central vertical and horizontal gaze pathways and vestibular systems may result in gaze palsies or nystagmus that the patient may report as visual difficulty.

Supranuclear Causes of Diplopia

INO due to lesion of the medial longitudinal fasciculus (MLF) is characterized by horizontal diplopia that is present in contralateral gaze only. Often, there is nystagmus of the abducting (normal) eye and slowed adducting saccade of the affected eye. Sometimes, this is the only finding. Adduction of the affected eye is often better during convergence because this does not use the MLF. INO localizes to the brainstem as is a common demyelinating syndrome. It can also result from small vessel stroke, sometimes, below the level of detection of diffusion weighted magnetic resonance imaging.

Skew deviation, a supranuclear disorder, is characterized by vertical diplopia with tilting of images in both eyes. Typically, it is associated with other vestibular or cerebellar symptoms and signs. Stroke and tumor are common causes.

Convergence insufficiency is trouble bringing the eyes in at near leading to horizontal diplopia when reading and is common in Parkinson disease and after concussion. Divergence insufficiency is trouble bringing the eyes apart leading to horizontal diplopia at distance. Both have similar symptoms in all directions of gaze, which distinguishes them from sixth nerve palsy and INO.

Third Nerve Palsy

A nonnuclear, third nerve palsy in isolation affects the superior rectus, inferior rectus, medical rectus, and inferior oblique (ie, all extraocular muscles except the superior rectus and lateral rectus) to cause oblique diplopia in primary gaze, vertical diplopia in up and down gaze, horizontal diplopia in contralateral gaze, and no diplopia in ipsilateral gaze. Additional localizing

signs are a larger ipsilateral pupil and ptosis. A nuclear third nerve palsy typically causes bilateral ptosis and bilateral upgaze deficits in addition to typical ipsilateral cranial nerve III signs.

Aneurysm compressing the ipsilateral third nerve is a can't miss diagnosis, which requires emergent angiographic imaging to exclude it. Uncal herniation, typically associated with altered mental status, causes pupillary dilation through third nerve compression. Skull base tumors can also cause third nerve palsy through compression. In chronic compression, there can be aberrant regeneration, which is demonstrated on exam when one third nerve action (eg lid raising), occurs when another (eg, downgaze) is attempted.

A common cause of isolated third nerve palsy in older individuals with vascular risk factors is a microvascular palsy that typically resolves in approximately 3 months. Ophthalmoplegic migraine can cause a transient third nerve palsy in children. These are diagnoses of exclusion without confirmatory diagnostic tests.

Brainstem parenchymal events such as stroke, demyelination, and tumor can cause third nerve palsy accompanying contralateral movement disorder (Benedikt syndrome), contralateral ataxia (Claude syndrome), or contralateral hemiparesis (Weber syndrome).

Fourth Nerve Palsy

A nonnuclear fourth nerve palsy in isolation affects the ipsilateral superior oblique muscle to cause vertical diplopia that is worse in down gaze, contralateral gaze, and ipsilateral head tilt. Due to the torsional action of the superior oblique, the image in the affected eye can appear tilted. Patients may adopt a compensatory head tilt. A nuclear fourth nerve palsy causes contralateral superior oblique dysfunction.

Brainstem causes of fourth nerve palsy can be accompanied by a contralateral Horner syndrome. Fascicular causes include microvascular, traumatic, and compressive. Fourth nerve palsies are a common childhood strabismus pattern that can decompensate in adulthood to cause new-onset diplopia.

Sixth Nerve Palsy

A nonnuclear sixth nerve palsy in isolation affects the lateral rectus muscle to cause horizontal diplopia in ipsilateral gaze that resolves in contralateral gaze. A nuclear sixth nerve palsy causes an ipsilateral gaze palsy (ie, affecting both eyes and therefore without diplopia).

Sixth nerve palsy is a false localizing sign of elevated ICP, for example, due to tumor, venous sinus thrombosis or meningitis, and intracranial hypotension as might occur from cerebrospinal fluid leak. As with third and fourth nerve palsies, it can be caused by microvascular disease, compression, trauma, and brainstem events.

The sixth nerve floats freely in the cavernous sinus and may be affected in isolation by disease in this region. It is affected in petrous apicitis in Gradenigo syndrome.

Multiple Cranial Neuropathies

There are a few conditions and locations where multiple ocular motor nerves can be impacted.

Wernicke encephalopathy from vitamin B_1 deficiency can affect eye movements in isolation as well as in association with ataxia, nystagmus, and encephalopathy. Empiric treatment is necessary as blood thiamine levels do not reflect body stores. Miller Fisher syndrome, associated with anti-GQ1b antibodies causes ophthalmoplegia as well as areflexia and ataxia. Imaging is typically normal.

Cavernous Sinus Syndrome

Complete or partial involvement of cranial nerves III, IV, VI, sympathetic pathways (Horner syndrome), and V1 and V2 localizes to the cavernous sinus. Any process that elevates venous pressure in the cavernous sinus can transmit this pressure to the orbit to cause significant orbital signs including proptosis and red eyes. Vision can be affected if the process extends superiorly to the optic chiasm or if blood flow to the eye is affected. A standard head computed tomography does not image this region adequately, and imaging studies protocolled for the sella or pituitary region are necessary.

Cavernous carotid fistula draining into the orbit is associated with a red, proptotic eye with ophthalmoplegia, possible vision loss, and a prominent superior ophthalmic vein on orbital imaging. Cavernous sinus thrombosis, often associated with adjacent sinus infection, can be bacterial or fungal and can progress rapidly to meningitis. Pituitary apoplexy can occur horizontally into one or both cavernous sinuses and is associated with vision loss if it extends superiorly to contact the chiasm or optic nerves. Patients are prone to acute adrenal insufficiency. Dermatologic tumors of the face can spread along sensory nerves to the cavernous sinus to impact ocular motor nerves.

Inflammation of the cavernous sinus can occur due to a variety of pathologies. Tolosa-Hunt describes the syndrome of painful ophthalmoplegia that can result from this. Because of overlap with other cavernous sinus disease including neoplasm, workup to exclude these, sometimes including biopsy, is often necessary.

Neuromuscular Junction

Neuromuscular junction disorders can affect extraocular muscles in isolation or combination. The pattern of diplopia depends on which muscles are involved and can imitate eye movement disorders from cranial nerve and supranuclear causes. If ocular misalignment does not result, the patient may not have diplopia.

Myasthenia gravis involves the eyes in a high proportion of cases and often initially presents with ocular motor symptoms of ptosis and diplopia. 30% to 50% of individuals who present with isolated ocular disease will progress to have systemic disease. Characteristic findings are variability in exam, worsening later in the day and muscular fatigability on exam.

In addition to eye movement limitations and ptosis, botulism is associated with systemic weakness, dilated pupils, and constipation. Lambert-Eaton myasthenic syndrome causes ptosis without prominent eye movement limitations.

Myopathies

Inflammation, weakness, or mass lesions of the extraocular muscles can cause eye movement limitations and misalignment if they are asymmetric. Thyroid eye disease is an inflammatory restrictive myopathy that most commonly causes esotropia, hypertropia, eyelid retraction, and proptosis.

Mitochondrial myopathies can impact the extraocular muscles in isolation (eg, chronic progressive external ophthalmoplegia) and may be detected incidentally as patients adapt to the symmetric, slow deterioration in eye movements. Identification

of pigmentary retinopathy or systemic myopathy is important so that appropriate cardiac screening can be undertaken.

AFFERENT AND EFFERENT DYSFUNCTION

Sellar Pathology

The chiasm lies above the sella, and the cavernous sinuses lie to other side. Thus, any expansion of sellar or suprasellar pathology readily impacts the afferent and or efferent visual pathways. Most of these will be subacute in onset due to slow growth of pituitary adenoma, craniopharyngioma, meningioma, or aneurysm. Acute onset of vision loss of ophthalmoplegia is concerning for pituitary apoplexy causing a pituitary tumor to suddenly expand.

Orbital Apex Syndrome

Complete or partial involvement of cranial nerves III, IV, VI, V1 and the optic nerve localizes to the orbital apex. Focal processes may not cause significant orbital signs and be very difficult to discern on imaging. The differential diagnosis is broad with most entities, for example, inflammatory lesions, tumor of foreign body, evident on neuroimaging. It is important to maintain a high suspicion for fungal infection in orbital apex syndrome cases with normal neuroimaging as this is a challenging diagnosis to confirm.

High Intracranial Pressure

High ICP can cause papilledema through compression of the optic nerve by high cerebrospinal fluid pressure in the optic nerve sheath and sixth nerve palsy due to tension on the nerve. This is a neurologic emergency both due to the possibility of high risk underlying cause and the risk of vision loss from optic neuropathy.

Delirium 11

Merrick E. Miles, Christina J. Hayhurst, and Christopher G. Hughes

KEY POINTS

1. Delirium is common among hospitalized patients, occurring in up to 50% of patients after stroke and 80% of patients with critical illness.
2. Development of delirium increases hospital length of stay and is associated with long-term cognitive impairment, disability, and mortality.
3. Prevention is paramount in the fight against delirium.
4. Treatment is focused on correcting causes and improving environmental factors. Pharmacologic therapy may be undertaken for symptom management.
5. Medications should be used judiciously due to uncertainty about their efficacy and their potential effect on patient's sensorium.

INTRODUCTION

Delirium is a clinical syndrome characterized by fluctuations in mental status caused by acute cerebral dysfunction. Patients present with inattention, disorganized thinking, disorientation, and/or altered levels of consciousness. Other symptoms associated with delirium include sleep disturbances, abnormal psychomotor activity, hallucinations, and emotional disturbances such as fear, depression, or anxiety. Patients may experience symptomatology that is hyperactive or hypoactive or fluctuate between both (mixed delirium). Although hyperactive delirium is more dramatic, hypoactive delirium is more common and much more underdiagnosed.

Development of delirium while in the intensive care unit (ICU) has been associated with increased cost, ICU length of stay, hospital length of stay, higher readmission rates, and long-term cognitive dysfunction. This risk is independent of preexisting comorbid conditions, severity of concurrent illness, and age. Additionally, duration of delirium has been shown to increase the relative risk of death by 10% per day of delirium.

Delirium is common among hospitalized patients. Upon admission, approximately 11% to 25% of elderly patients are delirious, and an additional 30% or so will go on to develop delirium. Delirium is even more frequent among critically ill patients; it is estimated that up to 80% of patients in the ICU experience an episode of delirium. Given the implications of an episode of delirium on patient outcomes, prevention and treatment is of utmost importance.

CAUSES OF DELIRIUM

The underlying mechanism of delirium or acute brain dysfunction has many proposed pathways. Systemic inflammation, cholinergic deficiency, and disturbances in other neurotransmitters such as serotonin and norepinephrine have been implicated in the development of delirium.

Risk factors for delirium can be characterized into patient factors, current illness factors, and iatrogenic causes, as outlined in Table 11.1. Baseline patient factors that have been associated with development of delirium include preexisting dementia, history of stroke, advanced age, frailty, and cardiopulmonary comorbid disease. Thus, patients with lower cognitive and physical reserve possess decreased capacity to maintain normal brain functioning in response to the acute stress of injury and hospitalization.

Clinicians are able to modify several risk factors for delirium by improving sleep hygiene and sedative regimens and avoiding medications that might trigger delirium. For instance, benzodiazepines, steroids, and anticholinergics are independent risk factors for development of delirium. Analgesic regimens, specifically opiates, do not have a clearly defined relationship with development of delirium. In fact, inadequate pain control is a risk factor for development of delirium, but data regarding the specific effects of opioids on delirium are inconsistent (although meperidine and morphine appear to confer increased risk). It appears that adequate pain control might be beneficial in protection against delirium, but use of opiates for sedation might place patients at risk for development of delirium.

EPIDEMIOLOGY

Delirium is common among all patient populations. In the surgical patient population, rates of delirium directly postoperatively can reach 45%, whereas those admitted to the hospital have rates between 32% and 50%. In the critically ill population, rates range from 30% to 50%, with those requiring mechanical ventilation reaching rates up to 80% of patients. After stroke, incidence of

TABLE 11.1 Clinical Risk Factors for Delirium

Patient Factors	Acute Illness	Iatrogenic Causes
Baseline cognitive impairment	High severity of illness	Deep versus light sedation
Advanced age	Hypoxemia	Sleep disturbances
Ischemic heart disease or congestive heart failure	Electrolyte disturbances	Anticholinergic medications
Frailty	Sepsis	Opiates (meperidine, morphine)
Prior stroke	Poor pain control	Mechanical ventilation
Depression	Atrial fibrillation	Steroids
Alcohol and drug abuse	Anemia	Benzodiazepines

delirium has been reported to range from 20% to 50%, depending on the age of the cohort studied and the type of stroke.

Older patients have a higher risk of delirium than their younger cohorts, which is reflected in the fact that 30% of those admitted to the hospital will experience delirium. In older cancer patients, 50% to 60% will experience delirium during their hospitalization. In patients aged 70 years and older who have undergone spine surgery, up to 40.5% developed delirium, which was associated with higher hospital charges. In the palliative care setting, 50% of patients experience delirium, and those at the end stage of life experience rates up to 85%.

PATHOBIOLOGY

The pathobiology of delirium is a continuously evolving field with current ongoing research. Currently primarily implicated in the pathophysiology of delirium is inflammation, endothelial dysfunction, blood-brain barrier breakdown, and neurotransmitter imbalance. These changes lead to neuroinflammatory processes, microglial activation, neuronal injury, and neuronal death in the central nervous system. Markers of these processes have been associated with acute brain dysfunction across a variety of patient populations.

Acetylcholine has also been associated with delirium, with elevated levels in the serum and decreased levels in the cerebrospinal fluid found in delirious patients. Importantly, acetylcholine helps to decrease the inflammatory cytokines released, and with its cerebrospinal fluid deficiency, this action is inhibited. Norepinephrine elevation has been associated with hyperactive delirium, and one study showed that patients receiving dopamine infusion were more likely to develop delirium. The serotonin precursor, tryptophan, found in elevated levels is associated with delirium.

Neuroanatomic changes that include brain atrophy and white matter changes have been witnessed in patients with delirium. Atrophy and white matter changes continue to persist even after hospital discharge and may be the cause of long-term cognitive impairment in these patients.

DIAGNOSIS

The gold standard in diagnosis of delirium is evaluation by psychiatrist using the criteria for delirium as outlined in the *Diagnostic and Statistical Manual of Mental Disorders*. However, this in-depth psychiatric evaluation is at times unavailable, or unnecessary, and evaluation can be done using the following guidance. Importantly, diagnosis of delirium should prompt a thorough investigation into the potential etiology of the acute brain dysfunction or encephalopathy that includes detailed history and physical exam findings.

Focused History

Causes of delirium such as drug ingestion, alcohol or drug withdrawal, metabolic derangements, and infection should be sought. Because features of delirium such as confusion or inattention may be present, history may be difficult to obtain from the patient. Assistance from staff or family members may be necessary. In addition, baseline cognitive and functional status of the patient should be obtained because this can help differentiate between dementia and delirium.

Focused Exam

Focal neurologic findings that could point to seizure activity or stroke should be sought. Physical exam should also look for possible sources of infection (eg, pneumonia or urinary tract infection) as the cause of the patient's acute change in mental status. In addition, physical exam findings suggestive of drug exposure may be useful. For example, anticholinergic exposure would reveal increased temperature, flushed dry skin, tachycardia, and pupillary dilation on exam.

Initial Laboratory Workup

In addition to a history and physical exam, other causes of changes in mental status should be sought. An electrolyte panel, blood count, and liver and thyroid function tests should be obtained. Additionally, infectious causes should be ruled out with appropriate testing such as chest radiograph, urinalysis, and culture data. Hypoxemia and hypercarbia should also be excluded as causes of confusion, which may require arterial blood gas analysis.

Arousal Level

A patient's level of arousal and content of consciousness need to be examined to evaluate for delirium. The first step is determining the patient's level of arousal through the use of Glasgow Coma Scale or a sedation scale. The Richmond Agitation-Sedation Scale (Table 11.2) and the Riker Sedation-Agitation Scale are commonly

TABLE 11.2 Richmond Agitation-Sedation Scale

Score	Term	Description
+4	Combative	Overly combative, violent, immediate danger to staff
+3	Very agitated	Pulls or removes tube(s) or catheter(s); aggressive
+2	Agitated	Frequent or nonpurposeful movements, fights ventilator
+1	Restless	Anxious but movements not aggressive/vigorous
0	Alert and calm	
−1	Drowsy	Not fully alert but has sustained awakening (eye opening/eye contact) to voice >10 s
−2	Light sedation	Briefly awakens with eye contact to voice (<10 s)
−3	Moderate sedation	Movement or eye opening to voice (but no eye contact)
−4	Deep sedation	No response to voice but movement or eye opening to physical stimulation
−5	Unarousable	No response to voice or physical stimulation

TABLE 11.3 Confusion Assessment Method

Diagnosis of delirium requires the presence of *both* features A and B and the presence of *either* feature C or D.

A. Acute onset or fluctuating course	Is there evidence of an acute change in mental status from baseline? Does the abnormal behavior: • Fluctuate over time? • Come and go? • Increase/decrease in severity?
B. Inattention	Does the patient: • Have difficulty focusing? • Become easily distracted? • Have difficulty keeping track of what is said?
C. Disorganized thinking	Is the patient's thinking: • Disorganized? • Incoherent?
D. Altered level of consciousness	Is the patient: • Alert (normal)? • Vigilant (hyperalert)? • Lethargic (drowsy but arousable)? • Stuporous (difficult to arouse)? • Comatose (unarousable)?

used tools that can be used to assess level of arousal, including in patients on mechanical ventilation. If the patient is determined to be unresponsive, then he or she is in a comatose state and cannot be assessed for delirium. Thus, assessment for delirium cannot occur if the patient has Richmond Agitation-Sedation Scale −4 to −5 or Riker Sedation-Agitation Scale of 1 to 2. If the patient is responsive to verbal stimuli, then delirium can be assessed using tools such as the Confusion Assessment Method (CAM), the Confusion Assessment Method for the ICU (CAM-ICU), or the Intensive Care Delirium Screening Checklist (ICDSC).

Delirium Assessment

Diagnosis of delirium relies on determination from the history and physical that the condition is an acute change in the patients' status. In patients who are not mechanically ventilated, the CAM (Table 11.3) can be used for diagnosis. The CAM assesses the patient for the key features of delirium such as an acute onset, fluctuating course, and inattention. It then assesses the patient for other symptomatology of delirium such as disorganized thinking or altered level of consciousness.

In critically ill or mechanically ventilated patients, the CAM-ICU (Table 11.4) and ICDSC (Table 11.5) have been validated. The CAM-ICU assesses the same four features as the CAM in an abbreviated manner more applicable to patients with critical illness: acute change or fluctuation in mental status, inattention, disorganized thinking, and an altered level of consciousness. The ICDSC uses eight diagnostic features; the diagnosis of delirium requires four or more features to be present.

Delirium is a heterogeneous syndrome of brain dysfunction and rarely presents as a single clinical entity. Pure hyperactive delirium is less common despite being the foremost perception of delirium to most clinicians. Patients with hyperactive delirium display prominent agitated motor behaviors such as pulling at lines/catheters and physically or verbally assaulting staff. In contrast, most patients are either hypoactive or have a mixed subtype. Hypoactive delirium is characterized by slow patient movements, decreased speed of cognition, and decreased alertness. It has been associated with worse outcomes compared to hyperactive delirium; however, patients are often overlooked because they are not displaying disruptive behavior. The mixed subtype is characterized by having both hyper- and hypoactive delirium within a 24-hour period.

TABLE 11.4 Confusion Assessment Method for the Intensive Care Unit (CAM-ICU)

Feature A plus B and either C or D present = CAM-ICU positive.

A. Acute onset or fluctuating course	• Is the patient different than his or her baseline? *or* • Has the patient had any fluctuation in mental status in the past 24 h?
B. Inattention	• Letters attention test: Say to the patient, "I am going to read to you a series of 10 letters. Whenever you hear the letter 'A,' indicate by squeezing my hand." SAVEAHAART or CASABLANCA or ABADABADAAY Errors are counted when patient fails to squeeze on the letter "A" and when patient squeezes on any letter other than "A." If greater than two errors, patient has inattention.
C. Altered level of consciousness	• Present if the RASS score is anything other than alert and calm or RASS 0.
D. Disorganized thinking	• Ask patient yes/no questions: 1. Will a stone float on water? 2. Are there fish in the sea? 3. Does 1 lb weigh more than 2 lb? Errors are counted when the patient incorrectly answers a question. • Have the patient follow commands: Say to patient "Hold this many fingers up." (Show two fingers to patient.) Have him or her repeat with the other hand using a different number of fingers. An error is counted if patient is unable to complete the entire command. If patient makes greater than one error, then he or she is positive for this feature.

Abbreviation: RASS, Richmond Agitation-Sedation Scale.

TABLE 11.5 Intensive Care Delirium Screening Checklist

1. Altered level of consciousness	
A. Exaggerated response to normal stimulation	RASS +1 to +4
B. Normal wakefulness	RASS 0
C. Response to mild/moderate stimulation	RASS −1 to −3
D. Response only to intense stimulation	RASS −4
E. No response	RASS −5
Assessment is terminated if patient is a RASS −4 or RASS −5.	
2. Inattention	
A. Difficulty in following commands	
B. Easily distracted by external stimuli	
C. Difficulty in shifting focus	
One point if any are present	
3. Disorientation	
Patient not oriented to person, place, or time	
One point if any are present	
4. Hallucinations or delusions	
A. Equivocal evidence of hallucinations or behavior due to hallucinations	
B. Delusions	
One point if any are present	
5. Psychomotor agitation or retardation	
A. Hyperactivity requiring the use of addition sedatives or restraints	
B. Hypoactivity or psychomotor slowing	
One point if any are present	
6. Inappropriate speech or mood	
A. Inappropriate, disorganized, or incoherent speech	
B. Inappropriate mood	
One point if any are present	
7. Sleep/wake cycle disturbance	
A. Sleeping <4 h per night	
B. Waking frequently at night	
C. Sleeping >4 h during the day	
One point if any are present	
8. Symptom fluctuation	
Fluctuation of any of the above items over the previous 24 h	
Total score is based on adding items up from 1 to 8. A score >4 is concerning for delirium.	

Abbreviation: RASS, Richmond Agitation-Sedation Scale.

Diagnosis of Delirium After Neurologic Injury

Diagnosing delirium in the neurologically injured patient remains an important part of care for this patient population. Those that are diagnosed with delirium have longer lengths of stay in the ICU and hospital, and this diagnosis has also been associated with worse functional independence and cognition.

When evaluating patients with neurologic injury, it should always be noted that mental status changes and positive delirium screening tests can also be contributed to underlying pathology and should be evaluated appropriately before assigning the diagnosis of delirium. A screening too is also best operationalized by comparing the patient's postinjury baseline status with subsequent neurologic exams and assessments.

Diagnosis of delirium in this patient population requires the ability to differentiate delirium from mental status changes from the underlying disease process. The CAM-ICU has been validated in neurocritically ill patients by comparing it to the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, criteria for delirium. The CAM-ICU proved to be 76% sensitive and 98% specific for the diagnosis of delirium after stroke. The positive predictive value was 91%. In patients with traumatic brain injury, the CAM-ICU proved to be 62% sensitive, 74% specific, and had a positive predictive value of 63%.

Electroencephalogram Findings in Delirium

The fluctuating state of awareness in delirium is accompanied by changes in the electroencephalogram. Changes in level of attention parallel the slowing of background electroencephalogram rhythms. There may be deceleration or complete loss of posterior background rhythm, global slowing, and intermittent rhythmic delta activity especially in the frontal regions. Triphasic waves may be present when metabolic encephalopathy is a contributing factor.

Delirium Versus Dementia: A Diagnostic Challenge

It is estimated that 4.5 million older Americans have Alzheimer disease. As the population continues to age, this number will continue to increase. The prevalence of delirium in hospitalized patients with coexisting Alzheimer disease is estimated at 60% to 89% of patients, and delirium in patients with preexisting dementia has been associated with long-term cognitive decline that persists for at least 5 years after discharge from the hospital. Diagnosis of delirium in patients with underlying dementia can be difficult; symptoms of delirium can be attributed to the underlying cognitive dysfunction and overlooked as new symptomatology. Trials for validating delirium assessment tools have either excluded or included few patients with underlying dementia; however, based on the available evidence, the CAM and CAM-ICU are currently considered the best available tools.

MANAGEMENT

Delirium is an urgent medical condition, and prompt review of possible causes or inciting factors should be performed. Underlying causes such as pain, metabolic derangements, infection, and hypoxemia should be sought and treated. Prevention and treatment consist of two broad categories: *pharmacologic symptom management* and *environmental optimization*. Prevention is of paramount importance and should be always a consideration in the care plan of a patient.

Once delirium sets in, the initial step in management is to ensure patient and staff safety. If the patient is exhibiting signs of hyperactive delirium and is trying to remove medically necessary devices, pharmacologic management is likely needed. If pain is an inciting cause, analgesic therapy with opioids or nonsteroidal anti-inflammatory drugs should be used as the first line of therapy. Symptomatic treatment is usually with dexmedetomidine or an antipsychotic medication such as haloperidol, olanzapine, or quetiapine (**Table 11.6**). Benzodiazepines can often exacerbate delirium symptoms and should be avoided unless the cause is alcohol withdrawal or if there is a component of severe anxiety. Despite common use among clinicians, no drug

TABLE 11.6 Medications Used to Control Delirium Symptoms

Drug	Dose
Dexmedetomidine (Precedex)	0.2-1.4 μg/kg/min IV infusion
Haloperidol (Haldol)	1-10 mg IV q4-6h
Olanzapine (Zyprexa)	5-10 mg by mouth q8h
Quetiapine (Seroquel)	25-400 mg q8-12h

Abbreviation: IV, intravenous.

has been approved by the U.S. Food and Drug Administration for prevention or treatment of delirium. Furthermore, although some smaller studies have found benefit, there is paucity of large randomized controlled trials that support the use of medications for the treatment of delirium. In general, agents that tend to be used to prevent or treat delirium affect the sensorium and have significant side effects. For example, antipsychotic agents can cause sedation, respiratory depression, prolonged QT intervals, and neuroleptic malignant syndrome.

Pharmacologic Prevention

First-line pharmacologic therapy for delirium prevention in the ICU consists mostly of appropriate sedation regimens. Sedative regimens that focus on targeted arousal levels and light sedation have positively affected the rates of delirium, and exposure to sedative medications and deeper levels of sedation have been associated with increased risk of delirium. The increased sedation intensity was also associated with higher mortality. Sedation should therefore be titrated to the minimal required amount to keep the patient comfortable and safe but awake.

The use of dexmedetomidine for sedation during mechanical ventilation has improved delirium outcomes in randomized controlled trials when compared to lorazepam, midazolam, propofol, and morphine. The Maximizing Efficacy of Targeted Sedation and Reducing Neurological Dysfunction trial compared lorazepam and dexmedetomidine for sedation in critically ill patients, and patients who received dexmedetomidine for sedation had more days free of delirium LEVEL 1.[1] The Safety and Efficacy of Dexmedetomidine Compared with Midazolam trial showed that patients sedated with dexmedetomidine achieved adequate levels of sedation while experiencing less episodes of delirium and shorter time to extubation LEVEL 1.[2] Dexmedetomidine for sedation after surgery versus propofol has shown decreased risk of delirium development and duration of delirium in patients receiving dexmedetomidine. However, a recent study compared patients undergoing mechanical ventilation in the ICU sedated with dexmedetomidine versus those receiving usual care (propofol, midazolam, or other sedatives). This study's primary outcome was all-cause mortality at 90 days, which showed no difference between the two groups. As a secondary cause, the study found no difference in the days spent without coma or delirium LEVEL 2.[3] This unblinded study was confounded by deeper levels of sedation, additional sedative use in 70% of the dexmedetomidine group, and delirium reduction was only a secondary outcome. Overall, studies support the use of dexmedetomidine for sedation to prevent delirium in mechanically ventilated ICU patients.

Prophylactic dexmedetomidine (compared to dexmedetomidine infusion for sedation) has been studied as a method to prevent delirium. Studies have shown this to be beneficial in older patients admitted to the surgical ICU after noncardiac surgery and as nocturnal administration in critically ill patients. Other studies, however, have not found benefit with prophylactic dexmedetomidine in older patients undergoing major noncardiac or cardiac surgery. The role of prophylactic dexmedetomidine after neurologic injury is unclear.

There are several randomized controlled trials examining the efficacy of antipsychotics for prevention of delirium, including haloperidol, olanzapine, and risperidone. For the most part, these studies have been small with low-study quality and have produced inconsistent results. Meta-analyses of antipsychotics for delirium prevention found no benefit. The more recent and larger prophylactic haloperidol use for delirium in ICU patients with a high risk for delirium (REDUCE) trial showed that prophylactic haloperidol versus placebo starting within 24 hours of ICU admission did not change the incidence of delirium, length of stay, or mortality LEVEL 3.[4]

Anti-inflammatory agents, including steroids and statins, have been of interest given the potential role of inflammation in delirium. Several large studies have not shown a benefit of steroid administration with regard to reducing delirium. Statin therapy while in the ICU has been shown in two studies to be associated with lower overall risk of delirium. Also, increasing duration of statin discontinuation in chronic statin users increased the odds of developing delirium, potentially from a rebound pro-inflammatory state from statin discontinuation. Randomized controlled trials of statin versus placebo, however, have not shown a decreased risk of delirium. Although cholinergic depletion is thought to play a role in delirium development, acetylcholinesterase inhibitors such as rivastigmine and donepezil have had disappointing results with regard to delirium.

Pharmacologic Therapy

Pharmacologic agents for the treatment of delirium should be restricted to the patient who has failed prevention strategies and who is a risk to self or others. The most popular pharmacologic treatments are antipsychotic medications (eg, haloperidol, olanzapine, quetiapine) and dexmedetomidine.

When haloperidol was compared to olanzapine for delirium treatment, there was no difference in length of delirium. In a small study of patients who required intravenous haloperidol, subjects were randomized to receive placebo versus quetiapine in addition to the haloperidol. The quetiapine group had a faster resolution of the first episode of delirium. Another small study of low-dose bedtime quetiapine in patients with delirium found a reduction in delirium severity. The largest and best study to date on antipsychotics for the treatment of delirium—Modifying the Incidence of Delirium United States study—found no difference between haloperidol, ziprasidone, and placebo with regard to delirium, mortality, length of stay, and additional outcomes LEVEL 2.[5]

A randomized controlled trial compared dexmedetomidine to placebo in patients with critical illness that had otherwise resolved but for whom weaning from mechanical ventilation was prevented by hyperactive delirium. Patients treated with dexmedetomidine had increased ventilator-free hours and faster resolution of their delirium symptoms. A nonrandomized study

examined the effectiveness of dexmedetomidine versus haloperidol as a rescue therapy for nonintubated ICU patients with hyperactive delirium. Patients receiving dexmedetomidine had faster resolution of delirium, less oversedation, and a shorter ICU length of stay without increased incidence of hemodynamic side effects. The overall failure rate of haloperidol was 43%, demonstrating the limited efficacy of antipsychotic agents in the treatment of delirium.

Environmental Optimization

Nonpharmacologic interventions have been shown to be beneficial in patients with delirium, and improving the environmental factors remains the first-line intervention for delirium prevention and treatment. These treatments include sleep hygiene and patient reorientation. A study in medical patients reduced the incidence of delirium by 40% by focusing on regulation of environmental factors LEVEL 1.[6] These factors included appropriate and early removal of catheters/restraints, nonpharmacologic sleep protocols, early mobilization, providing regular stimulating activities, and attention to hydration. Patients should have continuity of caregivers and be provided eyeglasses or hearing aids as needed to provide cognitive stimulation. In a randomized trial of early physical and occupational therapy in critically ill patients, patients in the early mobilization group had greater return to functional status at hospital discharge and shorter duration of delirium LEVEL 1.[7] Therapy typically progresses from passive range of motion to active range of motion, exercise in bed, sitting, standing, and walking depending on a patient's neurologic deficits, sedation level, and physical abilities. Sleep hygiene is important to the prevention of delirium because fragmented sleep has been associated with increased rates of delirium. A decrease in the incidence of ICU delirium has been demonstrated when sleep disruptions are minimized and normal circadian rhythms are promoted. Nonpharmacologic sleep aids should be used when capable and alternative sleep medications used only when necessary. In the ICU, bundles involving frequent assessment and control of pain, awakening and breathing trial coordination, light sedation, minimizing benzodiazepine use, delirium monitoring and management, early mobility, and family involvement (ie, the ABCDEF bundle) have been advocated to improve outcomes associated with delirium. Studies of the ABCDEF bundle across multiple hospitals have found that increased bundle compliance was associated with improved survival and increased the number of days alive without delirium or coma.

CONCLUSION

Delirium commonly occurs in hospitalized patients and is independently associated with worse outcomes. Early recognition of delirium may be achieved through active use of screening tools such as the CAM or CAM-ICU. Treatment should focus on nonpharmacologic therapy such as improvement in the patient's sleep/wake cycle, early mobility, removal of unnecessary lines/catheters, and frequent stimulating activities (Table 11.7). Pharmacologic therapy should be used when patient behavior places themselves or staff at risk. These therapies should be used judiciously because they have unproven efficacy and alter patient sensorium.

TABLE 11.7 Management Strategies for Delirium

- Ensure patient and staff safety. Pharmacologic management may be required in patients whose agitation may harm themselves or others.
- Rule out emergent causes of mental status change such as hypoxia, hypercarbia, drug withdrawal, seizures, cerebral edema, and new/worsening stroke.
- Perform focused history and physical exam including assessment of arousal level.
- Assess delirium with tools such as the confusion assessment method or confusion assessment method for the intensive care unit.
- Removal of catheters/restraints; promote sleep; perform early mobilization; glasses and hearing aids; eliminate unnecessary alarms and stimuli; medication review.
- Light sedation strategies with avoidance of benzodiazepines
- Establish a calm, reassuring environment and promote human contact, especially with loved ones.

Dementia and Memory Loss 12

Lawrence S. Honig and James M. Noble

KEY POINTS

1. A range of cognitive changes including normal cognitive aging, delirium, depression, and mild cognitive impairment/dementia may prompt an evaluation for memory loss.
2. The clinical history, often informed by a care partner, and neurologic exam are essential to formulating an appropriate differential diagnosis.
3. A workup includes laboratory tests and structural neuroimaging to rule out treatable and reversible causes of cognitive impairment.
4. Increasingly, fluid and imaging biomarker-based assessments have enabled more specific dementia diagnoses.

INTRODUCTION

Dementia is characterized by intellectual deterioration, with concomitant decline in independence and daily social or occupational functions.

With different dementia disorders, various cognitive domains may predominantly affect including memory, orientation, abstraction, learning ability, visuospatial perception, language functions, constructional praxis, and higher executive functions such as planning, organizing, and sequencing activities. By past convention, now loosened, a diagnosis of dementia required significant impairment of at least two cognitive domains.

In the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM*) versions I through IV-TR, there was a requirement that at least one of the affected cognitive domains be memory. This requirement, designed originally for Alzheimer disease (see Chapter 51), has been dropped in the most recent *DSM-5* with recognition of various dementias that do not initially or primarily involve memory, for example, frontotemporal dementia (see Chapter 52).

Dementia is diagnosed only when there is some significant decline in ability to function at home or at work. Dementia may be distinguished from mild cognitive impairment (MCI; see Chapter 50) in the requirement of significant impairment of independence in everyday activities such as occupational, social, or self-maintenance activities. The patient with MCI may have cognitive impairment in one or more domains, but this dysfunction is insufficient to cause functional impairment. For this reason, detailed analysis of the patient's need for help from others for simple activities of daily living (eg, toileting, food preparation, shopping, housework) is crucial.

Terminology and Classification

In the most recent *DSM-5*, the American Psychiatric Association has eliminated the term *dementia* in favor of major neurocognitive disorder. However, the distinction between dementia and MCI remains because it pertains to functional status. The *DSM-5* formulation is of "major" and "minor" neurocognitive disorders, depending on the degree of functional impairment. The major neurocognitive disorders are what were termed *dementias*, and the minor neurocognitive disorders represent types of MCI that may be precursors to dementias (see Chapter 50). The new *DSM-5* criteria permit both major and minor neurocognitive disorders to involve impairment with even a single domain but keep the distinction as to presence or absence of functional impairment. Despite the revised terminology of the *DSM-5*, the use of the terms *dementia* and *MCI* persisted in both neurologic care, lay audiences, and research.

Dementia can be classified in various ways. From the standpoint of clinical utility, dementia can be defined based on several features as a means to determine the differential diagnosis. These features include speed of progression, age of onset, and whether or not a reversible cause can be identified. The prior terminology of presenile (ie, young at onset) or senile (ie, old at onset) is no longer used because each of the dementing disorders can have first symptoms arise over a wide range of age at onset. However, age can be helpful in some cases of early-onset dementia (younger than 60 years of age) with a similar autosomal dominant family history given strong associations with several highly penetrant genes. Another dichotomous categorization of dementia proposed separating disorders into those of genetic origin and others of "sporadic" nature. However, this also has proven to be of minimal use because most dementia disorders may occur in either inherited (familial) forms or sporadic varieties, and some sporadic cases actually have a genetic basis. Dividing dementias into those with principally cortical or subcortical features, or into those with or without motor signs, has not proven useful for diagnosis, prognosis, or treatment and management. Thus, the most useful categorization of dementias is now based on the pathoetiologic basis of disease (Table 12.1). With clinicopathologic correlation, it is now usually possible to provide a specific diagnosis during life with 75% to 85% accuracy. It is important to recognize that even with an excellent clinical history and examination and auxiliary testing, clinical diagnosis of the dementia pathoetiology will not have perfect sensitivity or specificity.

Some patients have subjective complaints of cognitive disturbance, which is objectively verifiable but insufficient in either severity or functional disturbance or activities of daily life to meet criteria for dementia. In these cases, a diagnosis of MCI may be made, with specification of the involved cognitive domains (memory, language, visuospatial, executive, or attention). A large proportion of persons with MCI will develop some form of dementia within 5 to 7 years, with an annual rate of conversion of MCI to dementia as high as 10% to 15%.

Dementia Versus Mild Cognitive Impairment

Attempts have been made to better define cognitive changes associated with aging, and varying sets of criteria have produced multiple terms, including such terms as *age-associated memory*

TABLE 12.1 Dementias Categorized by Pathoetiologic Basis

Primary Neurodegenerative Disorders
Alzheimer disease (AD)
Lewy body disorders
Dementia with Lewy bodies (DLB)
Parkinson disease dementia (PDD)
Frontotemporal dementias (FTD)
Behavioral variant frontotemporal dementia (bvFTD)
Progressive nonfluent aphasia (PNFA)
Frontotemporal dementia with motor neuron disease (FTD-ALS, FTD-MND)
Progressive supranuclear palsy (PSP)
Corticobasal degeneration (CBD)
Huntington disease (HD)
Wilson disease (WD)
Creutzfeldt-Jakob disease (CJD) and other prion diseases
Hippocampal sclerosis
Limbic-predominant age-related TDP-43 encephalopathy (LATE)
Chronic traumatic encephalopathy (CTE)
Others: British familial dementia, HDLS, others
Vascular dementias: multi-infarct dementia, Binswanger disease, CADASIL
Immune-mediated encephalitides: NMDARAE, VGKCAE, others
Demyelinating dementias: multiple sclerosis, adreno- and metachromatic leukodystrophies
Inflammatory dementias: CNS vasculitides, Behçet syndrome, systemic lupus
Infectious dementias: neurosyphilis, neuroborreliosis, HIV dementia, others
Neoplastic dementias: tumors, carcinomatous meningitis, paraneoplastic syndromes
Metabolic or endocrine dementias: B_{12} or rarer vitamin deficiencies, hypothyroidism
Structural dementias: hydrocephalus, brain trauma

Abbreviations: CADASIL, cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy; CNS, central nervous system; FTD-ALS, frontotemporal dementia with amyotrophic lateral sclerosis; HDLS, hereditary diffuse leukoencephalopathy with spheroids; HIV, human immunodeficiency virus; NMDARAE, *N*-methyl-D-aspartate receptor antibody encephalitis; VGKCAE, voltage-gated potassium channel antibody encephalitis.

impairment, *age-related cognitive change*, and *questionable dementia*, among others. The most widely used term for cognitive change insufficient to meet criteria for dementia is *mild cognitive impairment* or, in the most recent psychiatric lexicon (*DSM-5*), *minor neurocognitive disorder* (see Chapter 50). Criteria for MCI include subjective cognitive complaints and objective cognitive dysfunction but preserved general cognitive function and activities of daily living. Follow-up examinations of individuals with MCI indicate that some, but not all, develop dementia over time.

Dementia Versus Delirium

As further reviewed in Chapter 11, delirium presents acutely or subacutely and is a state of mental confusion that, unlike dementia, is primarily characterized by inattention to the immediate environment. Dementia is insidious in onset, evolves over months to years with normal consciousness and progressively worsens, whereas delirium is acute in onset, evolving in days to weeks, with fluctuations in consciousness. Both dementia and delirium may involve anxiety, hallucinations, illusions, delusions, and dysautonomia. Delirium is often a consequence of diffuse systemic or cerebral insults, including pain, infections, intoxications, or withdrawal from medications or drugs of abuse, metabolic disorders including hepatic or renal dysfunction, hypoxemia, or other medical or neurologic diseases. It is not possible to diagnose dementia with certainty in the presence of delirium. Delirium in elderly hospitalized patients very often has an underlying substrate of a baseline dementing illness that becomes apparent once the delirium has resolved.

Several features help differentiate dementia from delirium. Attention is not usually impaired in patients with dementia, although it is almost always altered in delirium. Increased or decreased motor activity is inherent in delirium but absent usually in dementia. If the cause is identified, delirium itself can be reversed (although not necessarily an underlying dementia process), although most forms of dementia progressively worsen.

Dementia Versus Depression

Differentiating dementia from depression can sometimes be difficult. Depression (see Chapter 154) may be an early manifestation of Alzheimer disease. In depression, memory loss typically declines as the mood worsens. The onset of memory problems may be more abrupt than usually occurs in dementia and is mild, fluctuating, and nonprogressive. Neuropsychological test results may reflect variability or effort in performance and greater difficulties with learning, concentration, and attention, rather than true memory deficits such as seen with Alzheimer disease.

EPIDEMIOLOGY

Dementia increases in prevalence with age. Although uncommon in younger persons, with a prevalence of 1% by age 60 years, dementia becomes dramatically more common thereafter, with a prevalence of 50% or greater at age 90 years and older. In autopsy studies of individuals with dementia, about 70% to 80% of brains show pathologically definite Alzheimer disease (see **Table 12.2**). About half of these have concomitant pathology, with evidence of Lewy body involvement or cerebrovascular infarctions. Thus, only one-third of autopsy brains have "pure" Alzheimer disease.

PATHOBIOLOGY

Dementing disorders are best etiologically classified as endocrine, metabolic, cerebrovascular, inflammatory, infectious, structural, or neurodegenerative (see **Table 12.1**). The last category is characterized by absence of the prior-listed etiologies.

Neurodegenerative Dementias

In the United States, the most common causes of dementia of the elderly are neurodegenerative. These include Alzheimer disease, Lewy body dementia, frontotemporal dementia, and Creutzfeldt-Jakob disease (CJD).

TABLE 12.2 Prevalent Causes of Dementia in the Elderly

Alzheimer disease[a]	65%-85%
Lewy body disorders[b]	15%-30%
Frontotemporal dementias	5%-10%
Vascular dementias[c]	2%-10%
Other dementias	5%-10%

[a]Note that Lewy bodies may also be present in 20%-40% of cases.
[b]Note that concomitant Alzheimer disease is present in 55%-90% of cases.
[c]Note that infarcts are noted in ~35% of cases of dementia.

Alzheimer Disease

Alzheimer disease (see Chapter 51), with prominent memory and language impairment, is the most frequent form of dementia, accounting in the elderly for about 80% of the total number of patients in autopsy, clinical, or population-based series (Table 12.2). Structurally, it is marked by temporal and parietal degeneration. Molecularly, it is characterized as an "amyloidopathy" because the most specific hallmark is abnormal deposits of β-amyloid in plaques, in addition to the less specific hyperphosphorylated tau protein evident in neurofibrillary tangles. Recently described is limbic-predominant age-related TAR DNA-binding protein 43 (TDP-43) encephalopathy (LATE), in older adults, with or without coexisting hippocampal sclerosis pathology. Phenotypically LATE patients may appear clinically very similar to late-onset Alzheimer patients, although LATE tends to primarily involve the amygdala, hippocampus, and middle frontal gyrus and usually has a very slow course. Given that patients are older, copathology including Alzheimer changes are often present.

Lewy Body Dementia

Lewy body dementia is the second most frequent cause of dementia in the elderly (see Chapter 53), characterized clinically by parkinsonism, hallucinations, fluctuations in level of consciousness, and REM sleep behaviors. Pathologically, the presence of Lewy bodies with molecular composition principally alpha-synuclein has led to the term *synucleinopathy*.

Frontotemporal Dementias

Frontotemporal dementias represent a molecularly heterogeneous group of degenerative disorders marked by frontal and temporal degeneration (see Chapter 52). Frontotemporal degeneration often presents with onset of symptoms at younger ages, in the 50s, and accounts for 5% to 10% of cases. Manifestations typically consist of either frontal-type behavioral disturbances (eg, disinhibition, apathy, social impropriety, obsessions) or language disturbances. The molecular pathologies of this group of disorders can be broadly divided into those involving tau and those involving TDP-43 protein, with less common involvement of FUS, CHMP3, or VCP proteins. Pathologic entities including Pick disease, progressive supranuclear palsy (PSP), corticobasal degeneration (CBD), tangle dominant dementia, and argyrophilic grain disease are marked by prominent tau abnormalities and all now termed *tauopathies*. Motor neuron disease with dementia (amyotrophic lateral sclerosis dementia), some progressive aphasic disorders, and some behavioral variant frontotemporal dementias are TDP-43 proteinopathies.

Less Common Neurodegenerative Dementias

Other degenerative dementias include Wilson disease (see Chapter 139), a genetic disorder marked by copper deposition in the basal ganglia, dementia, and tremor, and Huntington disease (see Chapter 85), a genetic disorder marked by bicaudate atrophy, clinical dementia, chorea, and gait disorder. Even less frequent neurodegenerative dementing disorders include CJD (see Chapter 56), British familial dementia, neuroaxonal dystrophy, certain spinocerebellar ataxias, fragile X tremor ataxia syndrome, and others.

Vascular Dementia

Cerebrovascular disease was once considered to be a major cause of dementia of the elderly but is now recognized to be the principle cause of dementia in less than 5% of cases in the United States. Syndromes of strategic infarct dementia, multiple infarct dementia, severe ischemic white matter disease (Binswanger disease or subcortical arteriosclerotic dementia), and hemorrhagic brain disease may all cause dementia (see Chapter 54). Acute stroke is a common cause of cognitive impairment but does not present as a gradually progressive dementing illness; instead, cognitive deficits follow in the aftermath of acute focal neurologic deficits or may take a stepwise course with discrete episodes of impairment and disability.

Structural Causes of Dementia

The most common structural causes of dementia are chronic subdural hematoma (see Chapter 47), hydrocephalus (see Chapter 110), and brain tumors (Section 14). Both diagnoses are established, in part, by neuroimaging, such as computed tomography or magnetic resonance imaging (MRI), although imaging itself is not sufficient to determine the role of hydrocephalus in dementia. Subdural hematoma typically presents as progressive deterioration in cognition and gait over days to weeks. Headache and lateralized focal deficits may or may not be present. Hydrocephalus represents a relative increase in cerebrospinal fluid (CSF) in the cranial vault, causing compressive dysfunction of descending cortical pathways and cortex itself. The symptoms classically involve gait disorder, urinary incontinence, and dementia. Risk factors for hydrocephalus include prior history of intracranial hemorrhage, head injury, or meningitis, although these may not be known. Radiologically, distinguishing ventricular enlargement due to hydrocephalus from ventricular enlargement due to brain atrophy (hydrocephalus ex vacuo) can be challenging.

Metabolic Causes of Dementia

Metabolic causes of dementia include cobalamin (vitamin B_{12}) deficiency, hypothyroidism, hypercalcemic disorders, and rarer vitamin or endocrine deficiencies. Toxic disorders can include inhalant, mercury, or manganese poisoning. Inherited metabolic disorders that may lead to dementia in adults include Wilson disease, the adult form of ceroid lipofuscinosis (Kufs disease), cerebrotendinous xanthomatosis, metachromatic leukodystrophy, adrenoleukodystrophy, and mitochondrial disorders such as MELAS (mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes). Transient reversible memory loss may occur from acute medical illness, drug intoxications (most notably benzodiazepines), or from the poorly understood syndrome of *transient global amnesia* (see Chapter 64). This disorder typically occurs in older persons and consists of an acute circumscribed

period of time in which no new memories are acquired, with complete anterograde amnesia. Patients typically repetitively ask questions about their current situation.

Infectious Causes of Dementia

Infectious causes of dementia are less common in the developed world and mostly more frequent in the younger population. CJD, which results from prion protein infiltration of the brain resulting in a spongiform encephalopathy (see Chapter 56), is the most notorious potentially infectious cause of dementia, although it is only transmissible by direct exposure to diseased nervous system tissue. Viral disorders include human immunodeficiency virus (HIV)-associated dementia or herpesvirus family disorders (herpes simplex virus, varicella-zoster virus, cytomegalovirus, Epstein-Barr virus, human herpesvirus 6). Bacterial disorders include spirochetal disorders neurosyphilis and neuroborreliosis (Lyme disease) and atypical bacterial infections (tuberculosis). Fungal infections include meningitides owing to infection with *Cryptococcus*, *Coccidioides*, histoplasmosis, or others.

Dementia From Endocrine Dysfunction

Undiagnosed hypothyroidism is the most common endocrine abnormality that can present as dementia. Other endocrine disturbances that can cause dementia include Addison or Cushing disease, repeated episodes of hypoglycemia in diabetics, hyperparathyroidism associated with hypercalcemia, and hyperthyroidism (see Chapter 122). Hashimoto encephalopathy is a rare autoimmune encephalitis that occurs in conjunction with autoantibodies to thyroid proteins (see Chapter 74).

Inflammatory Causes of Dementia

Rapidly progressive dementia can be caused by the immune-mediated encephalitides (see Chapter 74), some of which are paraneoplastic disorders.

DIAGNOSIS

Focused History and Differential Diagnosis

The first symptoms of dementia often include occasional forgetfulness, misplacing objects, and word-finding difficulties (Table 12.3). With aging, a decline in memory may be observed, and thus sometimes, the distinction between cognitive decline in old age and early dementia may be difficult. By definition, dementia is associated with progressive decline in functioning and thus is distinguished from a static encephalopathy such as mental retardation or congenital syndromes. Important exclusionary criteria for dementia include syndromes that are better explained by delirium (see Chapter 11) or by a primary psychiatric disorder such as major affective disorder or schizophrenia.

Questions to Ask

Evaluation of complaints of cognitive dysfunction, whether described by the affected person or by a family member or caregiver, are first elicited by obtaining a thorough history. Particular attention should be paid as to which symptoms predominated at onset. Symptoms of memory loss (whether short term or long term), language usage (word-finding problems or decreased fluency, comprehension, or naming), praxis (dressing, use of utensils, or use of mechanical devices such as telephone or remote electronic controls), executive function (disorganization), insight (such as failure to recognize symptoms), dyscalculia, or behavioral dysfunction (agitation, disinhibition, depression, obsessions, delusions, or hallucinations) should be elicited. Symptoms of motor or gait impairment, adventitious movements, autonomic involvement (hypotension, urinary or bowel dysfunction), or sleep disturbance (evidence of rapid eye movement sleep behavior disorder, fractured sleep, and sleep apnea) should also be elicited.

TABLE 12.3 Ten Warning Signs of Alzheimer Disease[a]

1. Memory loss that affects job skills
2. Difficulty performing familiar tasks
3. Problems with language
4. Disorientation to time and place
5. Poor or decreased judgment
6. Problems with abstract thinking
7. Misplacing things
8. Changes in mood or personality
9. Problems with directions or spatial relations
10. Loss of initiative

[a]Adapted from the Alzheimer's Association. 10 early signs and symptoms of Alzheimer's. Alzheimer's Association Web site. https://www.alz.org/alzheimers-dementia/10_signs. Accessed October 15, 2020.

Focused Examination

Mental Status Examination

The mental status evaluation is an essential part of every neurologic examination but particularly so in the evaluation of patients with cognitive symptoms. Much of the evaluation is predicated on an attentive and communicative patient. Thus, the evaluation starts with determination of level of consciousness, alertness, and attention and proceeds to basic ascertainment of expressive and receptive language. If these are not intact, the evaluation is necessarily difficult and limited. A broad overview of the mental status examination is covered in Chapter 4. General assessments include the following:

- Awareness and consciousness
- Verbal behavior including appropriateness
- Motor behavior including agitation or picking movements
- Mood and emotional state

More specific cognitive assessments include the following:

- Orientation to time (hour, day, date, month, year, season) and place (institution, address, floor, city, state)
- Concentration (eg, spelling a five-letter word in reverse, counting backward by serial 7s, reciting the months of the year in reverse)
- Detailed language testing (expressive speech; aural and reading comprehension of one-, two-, or three-step commands; naming of solid objects or drawings; repetition of easy or difficult [prepositional] phrases; reading comprehension; ability to write a sentence)
- Registration or immediate recall (of three or five objects or words)

- Short-term memory or delayed recall after 3 to 10 minutes of three or five objects or words
- Long-term memory or fund of knowledge (names of current and prior elected officials, birthdates of family members, items of history)
- Visuospatial constructive abilities (copying simple shapes)
- Arithmetic calculations (mentally summing the values of coins, simple one- or two-digit additions or subtractions)
- Abstract reasoning (defining similarities, interpreting proverbs)
- Motor sequencing and praxis (sequential movements and motor commands)

Bedside Standardized Cognitive Testing

Two widely used brief standardized cognitive assessments are the Mini-Mental State Examination (MMSE) and the Montreal Cognitive Assessment (MoCA). These tests were introduced as standard measures of cognitive function for both research and clinical purposes. They are short, requiring less than 10 minutes, relatively easy to administer, and result in scores of 0 (failing all items) to 30 points (perfect score).

It is important to emphasize that the MMSE and MoCA, like all brief mental status exams, are not perfectly sensitive or specific for dementia. These tests are sensitive to cultural and language factors and level of education. Well-educated patients may suffer from dementia and nonetheless score a "perfect" 30 points on these 30-point scales, whereas poorly educated patients may score much lower and yet be nondemented. Therefore, the MMSE or MoCA should be used as screening instruments, but they do not replace a detailed history and examination or full neuropsychological testing (see Chapter 31).

General Neurologic Examination

The general neurologic examination is useful in the evaluation of the patient with dementia because certain signs (Table 12.4) may make a diagnosis of Alzheimer unlikely and may point to another causative etiology. For example, focal findings of hemiparesis may suggest a vascular component or, in cases of hemineglect, the degenerative disorder CBD. Prominent visual dysfunction may suggest posterior cortical atrophy, usually a variant of Alzheimer disease. Paralysis of supranuclear gaze with preserved brainstem reflexes may suggest PSP or CBD. Symmetric parkinsonism could support Lewy body dementia, PSP, or CBD. Lower motor neuron signs, such as fasciculations and atrophy, may suggest frontotemporal dementia with motor neuron disease. Primitive reflexes, although often checked, are commonly seen in dementia of any cause but also can be seen in normal aging.

Diagnostic Testing

The American Academy of Neurology in 2001 developed the evidence-based practice parameters for evaluation of the diagnosis and cause of dementia. These parameters have been entirely revolutionized by the development of modern neuroimaging, biomarkers, and genetic tests. A workgroup formed by the National Institute on Aging in conjunction with the Alzheimer's Association published in 2011, revised recommendations on diagnostic criteria, which are included in Table 12.5.

Neuropsychological Testing

Detailed neuropsychological testing (see Chapter 31) may be performed to augment the clinical mental status examination by assessing severity and regional pattern of cognitive impairment through use of standardized tests with normative values. This can be very helpful not only in differential diagnosis but also in monitoring disease progression.

Memory impairment can be parsed into immediate or working memory, short-term memory, and remote memory. Working memory is typically unaffected in early Alzheimer disease but often significantly affected in depression and subcortical dementias such as Parkinson disease dementia. In contradistinction, short-term recall is severely and early affected in Alzheimer disease and its precursor, amnestic MCI. Remote or long-term memory is affected later in the disease course of Alzheimer disease but may be relatively preserved even late in the course of some of the other dementias.

Language impairments can be assessed. Naming difficulties, common in Alzheimer disease, are less common in subcortical dementias. Verbal fluency for categories (semantic verbal fluency) is much more severely affected in disorders of the temporal lobes, such as Alzheimer disease, compared to verbal fluency for letters (phonemic verbal fluency), which is more affected in disorders of the frontal lobes, such as frontotemporal dementia.

Visuospatial impairments can be assessed. Typically, visuoperceptive impairment is marked in Alzheimer disease, whereas disorganization is more prominent in frontotemporal dementias. Micropraxia (drawing very small shapes) is common in the Lewy body disorders.

TABLE 12.4 Neurologic Signs and Symptoms Atypical for Alzheimer Disease

Sign or Symptom	Possible Significance
Dominant nonmemory features (eg, language, praxis, visuospatial dysfunction)	Frontotemporal degenerations, posterior cortical atrophy
Prominent behavioral, personality, psychotic symptoms	Frontotemporal degenerations, Lewy body dementia
Early parkinsonism (eg, resting tremor, bradykinesia, cogwheeling)	Lewy body dementia, progressive supranuclear palsy (no rest tremor), corticobasal degeneration, hydrocephalus
Urinary incontinence	Hydrocephalus
REM sleep behavior disorder	Parkinson disease dementia, Lewy body dementia
Seizures	Immune-mediated or infectious encephalitides
Myoclonus	Creutzfeldt-Jakob disease
Frequent falls	Progressive supranuclear palsy
Early unexplained gait abnormalities	Lewy body dementia, progressive supranuclear palsy, corticobasal degeneration, hydrocephalus
Early prominence of bulbar/brainstem signs	Progressive supranuclear palsy
Unexplained motor or reflex asymmetries	Vascular dementia, corticobasal degeneration
Unexplained (early) UMN signs (eg, Babinski sign)	Frontotemporal degeneration with motor neuron disease
Unexplained LMN signs (eg, fasciculations)	Frontotemporal degeneration with motor neuron disease

Abbreviations: LMN, lower motor neuron; REM, rapid eye movement; UMN, upper motor neuron.

TABLE 12.5 Practice Parameters for Diagnosis of Dementia[a]

Clinical Evaluation
History from patient and an informant
Cognitive assessment—mental status examination
Neuropsychological testing (when above is insufficient for confident diagnosis)
Routine Testing
Complete blood cell count
Serum chemistry—electrolytes, glucose
Serum BUN, creatinine, liver function tests
Serum TSH and B_{12} level
Serologic tests for syphilis and HIV (optional—depending on risk)
Biomarkers
Measures of brain atrophy, infarction, and structural changes
Brain MRI
Measures of neurodegeneration or neuronal injury
CSF total tau measurement
FDG-PET
MRI regional volumes and grey matter thickness
Measures of β-amyloid
CSF β-amyloid measurement
PET amyloid imaging
Measures of neurofibrillary tangles
CSF phospho-tau measurement
PET tau imaging
Measure of dopaminergic dysfunction
Ioflupane SPECT scan
Genetic tests (depending on age, family history, and clinical presentation)
AD mutations: PS1, PS2, APP
FTD mutations: tau, C9orf, progranulin
Prion protein mutations
Other mutations

Abbreviations: AD, Alzheimer disease; APP, amyloid precursor protein; BUN, blood urea nitrogen; C9orf, Chromosome 9 Open Reading Fram; CSF, cerebrospinal fluid; FDG, ^{18}F-fluorodeoxyglucose; FTD, frontotemporal dementia; HIV, human immunodeficiency virus; MRI, magnetic resonance imaging; PET, positron emission tomography; PS1, presenilin 1; PS2, presenilin 2; SPECT, single photon emission computed tomography; TSH, thyroid function tests.

[a]This table is based on first practice guidelines published by American Academy of Neurology (2001), more recent National Institute on Aging-Alzheimer's Association Workgroup recommendations (2011), and other practice guidelines.

Laboratory Blood Testing

Recommendations for auxiliary testing generally include basic laboratory tests (blood chemistry and cell counts) and, more specifically, laboratory testing for vitamin B_{12} deficiency (with homocysteine and methylmalonate ordered if B_{12} is borderline or low) and thyroid deficiency (thyroid-stimulating hormone [TSH], with free T4 ordered if TSH is out of normal range). The American Academy of Neurology guidelines specify B_{12}, TSH, and structural imaging (generally MRI) to exclude contributory disorders to cognitive symptoms, which might be otherwise unrecognized LEVEL 7.[1] Serologic tests for exposure to syphilis (Venereal Disease Research Laboratory and fluorescent treponemal antibody-absorption test), Lyme disease (screening enzyme immunoassay, with confirmatory Western blots), or HIV (HIV-1/HIV-2 antibody and antigen) may be of value.

Laboratory Cerebrospinal Fluid Testing

Analysis of CSF obtained through lumbar puncture (see Chapter 32) is increasingly used in diagnosis of cognitive dysfunction. CSF provides information in two broad categories: (1) In an exclusionary fashion, it may be used to be certain that various infectious or inflammatory etiologies of dementia discussed earlier are not present, and (2) in an inclusionary fashion, it may provide information with regard to neurodegenerative diseases, such as Alzheimer disease or CJD, through use of protein biomarkers (see Chapter 32). Presence of abnormal numbers of leukocytes, taking into account any blood contamination, is typically indicative of an inflammatory or infectious process. Biomarkers including β-amyloid-42, total tau, phosphotau, and 14-3-3 protein are established as of use in the diagnosis of Alzheimer disease and CJD. In Alzheimer disease, typically β-amyloid-42 is lower than normal, total tau is higher than normal, and phosphotau is higher than normal. These changes are often the earliest biomarker of Alzheimer disease and may be evident prior to clinical symptoms and prior to structural and functional neuroimaging changes seen by MRI or positron emission tomography (PET) scans. Currently, these biomarkers are being increasingly used not only for their diagnostic value but also to potentially provide surrogate indices of dementia severity and progress. For CJD, typically both total tau and 14-3-3 are highly elevated. CSF biomarkers not only may yield improvements in the differential diagnostic process but also allow better assessment of change during investigational therapies designed to affect disease symptoms or modify the disease process (Table 12.6).

Neurophysiologic Testing

Electroencephalogram testing can be useful in two contexts: (1) It may assist in the assessment of the possibility of subclinical paroxysmal disorders being responsible for abnormal mental status and (2) it may be of use in cases where it is less clear whether a primary psychiatric or neurologic diagnosis explains the clinical presentation. Epileptiform activity may be particularly prominent in the immune-mediated encephalitides or other

TABLE 12.6 Dementias Categorized by Protein Pathologies

β-Amyloidopathy	AD
α-Synucleinopathy	Lewy body disorders (DLB), PDD
Tauopathy	Frontotemporal dementia: Pick disease, PSP, CBD (Note that AD has secondary tau pathology.)
TDP-43 proteinopathy	Frontotemporal dementia (FTD-U), ALS with dementia
Prionopathy	Creutzfeldt-Jakob disease, sporadic/familial fatal insomnia, GSS, vCJD

Abbreviations: AD, Alzheimer disease; ALS, amyotrophic lateral sclerosis; CBD, corticobasal degeneration; DLB, dementia with Lewy bodies; FTD-U, FTD with ubiquitinated inclusions; GSS, Gerstmann-Sträussler-Scheinker disease; PDD, Parkinson disease dementia; PSP, progressive supranuclear palsy; TDP-43, TAR DNA-binding protein 43; vCJD, variant Creutzfeldt-Jakob disease.

rapidly progressive dementias such as rabies or herpes simplex encephalitis. In disorders that are purely psychiatric, frequently background EEG rhythm may be normal, whereas conversely neurologic disorders may be accompanied by focal or generalized background slowing.

Electromyography provides an assessment of the lower motor neurons, which can be helpful in ascertaining the presence of frontotemporal dementia with motor neuron disease. Sensory nerve studies may be helpful in rarer disorders such as metachromatic leukodystrophy.

Neuroimaging

Conventional Computed Tomography and Magnetic Resonance

Structural neuroimaging can be useful in both exclusionary and inclusionary fashions with respect to neurodegenerative dementias. Discovery of significant vascular injury, inflammatory lesions, contrast-enhancing processes, or tumors may be decisive in ruling out degenerative processes and indicating some infectious, inflammatory, or neoplastic process. However, even in cases of "radiologically normal" scans, structural features such as parietal atrophy or temporal atrophy may be indicative of an Alzheimer process. Specialized imaging such as gradient echo (or susceptibility weighted imaging) sequences can reveal microhemorrhages, which when multiple may be suggestive of amyloid angiopathy, cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy, or hypertensive cerebrovascular injury. Other specialized sequences such as diffusion-weighted imaging may show strong evidence of prion disease. CJD typically results in diffusion-weighted hyperintensities in cortical regions confined to the gray matter cortical ribbon and also to the deep gray nuclei, including thalami, caudate, and lenticular nuclei.

Biomarker Imaging

Nuclear medicine imaging provides useful information in cases of suspected dementia. Single-photon emission computed tomography imaging (see Chapter 23) using technetium 99m–hexamethyl propylene amine oxime (HMPAO) or technetium 99m–ethyl cysteine dimer allows imaging of brain perfusion. These tests, as well as ^{18}O-PET, which also images brain blood perfusion, and more frequently used ^{18}F-fluorodeoxyglucose PET imaging (see Chapter 23), which images the closely linked feature of brain glucose metabolism, can be of value in displaying topographic patterns of brain dysfunction. These patterns can be relatively disease-specific. Typically, Alzheimer disease shows a pattern of biparietal and bitemporal hypoperfusion, or hypometabolism, that may be more or less asymmetric. There is sparing of the primary cortices including sensory, motor, and visual regions, as well as the deep gray nuclei. Lewy body disease shows a similar pattern but often with less prominent temporal involvement and much more parietal and occipital involvement, often involving the visual cortices. Frontotemporal dementias typically involve frontal and/or anterior temporal regions, sometimes quite asymmetrically, with preservation of parietal and other posterior regions. Most recently, the expanding field of molecular imaging has provided more specific imaging biomarker tools for neurodegenerative disorders. Assistance with diagnosis of Lewy body disorders may be provided, albeit with less than excellent sensitivity or specificity, through dopamine transporter imaging, such as iodine 123–joflupane single-photon emission computed tomography. The use of amyloid imaging, including ^{18}F-florbetapir, ^{18}F-florbetaben, and ^{18}F-flutemetamol, has allowed in vivo assessment in humans of fibrillar β-amyloid, indicating an Alzheimer process. Currently, this testing has high sensitivity but low specificity because many clinically unaffected individuals older than age 65 years may show evidence of amyloid deposition as determined by binding of these radiopharmaceutical tracers imaged using PET. However, additional molecular imaging tools such as the tracer ^{18}F flortaucipir specific for the tau protein aggregated in neurofibrillary tangles provide additional in-vivo diagnostic clarity and permit monitoring of progression of Alzheimer disease.

TREATMENT

For many forms of dementia, treatments are symptomatic and palliative. Recent advances suggest that disease modifying treatments, at least for Alzheimer's disease, are on the horizon. Some causes of dementia, such as vascular dementia, reducing the risk of recurrent stroke, and thus subsequent cognitive decline due to worsening stroke burden, may be possible through routine measures including targeted risk reduction of vascular risk factors. Treatments for specific conditions including depression, metabolic abnormalities, and autoimmune causes of dementia are directed at the underlying problem and are reviewed in their respective treatments. For all patients, particularly those with neurodegenerative causes of dementia, treatments are prioritized and directed to the primary symptoms impacting day to day life, through both pharmacologic and nonpharmacologic strategies aiming to help both the patient and the family unit through disease transitions. Further descriptions of treatment for neurodegenerative dementias are described in their respective chapters.

OUTCOME

Outcomes of various forms of dementia are highly variable patient to patient even within specific diagnostic categories, particularly neurodegenerative dementias. Factors determining longevity and mortality include comorbidities at the time of onset, support infrastructure, and patient-centered goals of care. Although uncommon, reversible causes of dementia may not have an appreciable impact on mortality and presumably will not recur if the underlying factor (ie, cobalamin deficiency, hypothyroidism, depression, or autoimmune causes, among others) are effectively treated.

Involuntary Movements 13

Sara M. Schaefer and Elan D. Louis

KEY POINTS

1. A careful history is key when a patient presents with involuntary movements, including the determination of duration, involved body part, exacerbating and relieving factors, and associated symptoms.
2. The movement disorders examination relies on attention to detail, prolonged observation of the patient in various configurations, and integrating the history and examination to perform tailored maneuvers.
3. Involuntary movements should first be described using basic terms (eg, *rhythmic*) to identify the correct phenomenology (eg, tremor) and guide the practitioner toward the appropriate diagnosis (eg, essential tremor).
4. Movement disorders may arise from anywhere in the neuraxis.
5. Treatment of movement disorders involves identifying and treating the underlying etiology, as applicable. Symptomatic treatment should be tailored to what is bothering the patient rather than what is observable on examination.
6. There are several movement disorders emergencies that require quick and accurate diagnosis because immediate intervention is critical to reduce associated morbidity and mortality.

INTRODUCTION

Approaching abnormal involuntary movements is a multidimensional process that relies first on a careful history and a detailed examination.

FOCUSED HISTORY

The neurologic history is an important first step in arriving at the correct diagnosis (Table 13.1). It is important to ask the patient about the location of the movements. Some patients may feel the movements in body parts that are not visibly shaking. The periodicity of the movements is an important historical clue, as some movement disorders are by definition paroxysmal (eg, paroxysmal dyskinesias, episodic ataxias, paroxysmal hypnogenic dyskinesias, or transient dyskinesias of infants). The items that exacerbate and/or relieve the movements may point toward a particular diagnosis, such as exercise in paroxysmal kinesigenic dyskinesias or a sensory trick in dystonia. The conditions during which the movements occur (eg, at rest or with movement) are also of importance in tremor classification, and accompanying feelings of restlessness, urges to move, ability to suppress the movements, and relief after the movement are important features to consider when diagnosing tics, akathisia, and restless legs syndrome. The provider should assess for any associated features such as vocalizations that may accompany the movements, as may be seen in tics or hyperekplexia or pain or pulling sensation that may indicate abnormal muscle contraction/spasm as seen in dystonia. Family history is also vital to collect, and it may be instructive to examine additional family members; several movement disorders display Mendelian genetic inheritance (eg, Huntington chorea), whereas others tend to run in families (eg, essential tremor). It is important to obtain a list of current

TABLE 13.1 Questions to Ask the Patient Who Presents With Involuntary Movements

Question	Relevant Involuntary Movement
Where (ie, in what body regions) are the movements?	All
Are the movements periodic?	Paroxysmal movement disorders
Does anything (eg, movement, startle) trigger or exacerbate the movements?	Paroxysmal movement disorders, hyperekplexia, dystonia
Is there a sensory trick (a place they can touch to lessen the movement)?	Dystonia
Do movements occur at rest or with action?	All
Is the patient feeling restless?	Tics, akathisia, restless legs syndrome
Is there an urge to move?	Akathisia, tics, restless legs syndrome
Is the patient able to suppress the movements?	Akathisia, restless legs syndrome
Does the movement produce a feeling of relief?	Tics, akathisia, restless legs syndrome
Are there accompanying vocalizations?	Tics, hyperekplexia
Is there pain/discomfort in the region where the movements are occurring?	Dystonia (especially cervical dystonia)
Is there a pulling feeling in the muscles?	Dystonia (especially cervical dystonia)
Is there a family history?	Paroxysmal movement disorders, dystonia, tremor, tics, hyperekplexia, chorea, ataxia
What are the current medications?	All
What were the past medications (eg, dopamine blockers)?	Tardive movements

medications (as these may be producing, exacerbating, or partially suppressing movements) as well as medication exposures in the past (especially medications with dopamine blockade).

FOCUSED EXAMINATION

Visual inspection of the patient with a thorough and careful neurologic examination is of central importance when assigning a movement disorders diagnosis. The neurologic examination is the most important tool for the diagnosis of involuntary movements. To begin with, it is important to spend time observing the patient and visualizing the movements. Tell the patient that you are going to watch their movements and then sit in front of them and observe. Patients may sometimes be self-conscious and may try to inhibit their involuntary movements, particularly if these movements are embarrassing. If this is the case, then ask the patient to just let their body "do what it wants to do . . . don't try to stop it." After the observation, it is important to ask the patient to perform certain maneuvers designed to bring out the movement (eg, writing may bring out a tremor, heel-to-shin maneuver may bring out asynergia, and walking may bring out a dystonic foot movement). A careful history can inform tailored examination techniques; for example, if a patient reports that a certain maneuver brings out or alleviates the movement, one can incorporate it into the examination. Some movements may be quite elaborate, and the examiner may need to observe for quite some time before being able to detect a consistent pattern or before being able to fully encapsulate and describe the phenomenology.

DESCRIPTION OF INVOLUNTARY MOVEMENTS

When examining a patient, the examiner must first decide whether the abnormal movement is hyperkinetic or hypokinetic. *Hyperkinetic* refers to movements in excess of normal, whereas *hypokinetic* is a paucity of movement.

Hypokinetic movements may be slow (*bradykinesia*), small (*hypokinesia*), or absent (*akinesia*). Although these terms have specific meanings, as noted earlier, they are often used interchangeably; in practice, *bradykinesia* is often used as an umbrella term that encompasses all of these entities. Paucity of movement due to weakness (such as from a stroke) is not included in the hypokinetic definition. The most ubiquitous movement disorders that are characterized by hypokinetic movements are parkinsonisms, which—along with resting tremor, rigidity, and postural instability—are partially defined by bradykinesia/akinesia. Bradykinesia may manifest during numerous aspects of a patient's examination; these include ambulation (eg, decreased stride length and arm swing), phonation (eg, hypophonia), writing (eg, micrographia), repetitive movements (eg, slow finger taps), and spontaneous gesturing (eg, global bradykinesia). The blink rate may be slow, and the face may be poorly expressive (hypomimia). In parkinsonism, not only are the movements slow and small, but the examiner often sees a decrement of speed and amplitude over time. This phenomenon may be seen with repetitive movements such as finger or toe tapping or even during handwriting and spiral drawing (the letter amplitude gets smaller as the patient writes or the lines get closer together as the patient draws the spiral). Furthermore, hesitation and freezing phenomena (ie, delays and interruptions of movement) are frequent features of parkinsonian states.

The inverse of hypokinetic movements is hyperkinetic movements. Just as hypokinetic movements do not include those related to weakness, hyperkinetic movements do not include those related to convulsions, neuromuscular dysfunction (fasciculations), or reflex clonus—these are abnormal involuntary movements that are categorized elsewhere due to their etiologies. When describing a hyperkinetic movement, one should start with basic descriptors (eg, oscillatory, flowing) to determine the correct phenomenology (eg, tremor, chorea) and reach the appropriate diagnosis (eg, essential tremor, Huntington disease) (**Fig. 13.1**).

Several categories of descriptors may be used: level of voluntariness, rhythmicity, pattern (stereotyped vs. nonstereotyped), and texture (ie, look and feel of the movement) (**Fig. 13.2**). The essence of each phenomenologic diagnosis may originate from some or all of these categories. Tremor, for example, is an involuntary, rhythmic, oscillatory movement. See **Table 13.2** for explanations of each of these terms.

TYPES OF HYPERKINETIC PHENOMENOLOGIES

There are a number of abnormal hyperkinetic phenomenologies (**Table 13.3**), and each of these are described further in the following text.

FIGURE 13.1 Flow diagram of the process of evaluating an involuntary movement, from description to diagnosis.

FIGURE 13.2 Descriptive terms for involuntary movements by category.

Myoclonus

Myoclonus (see Chapter 81) refers to a fast (less than 100 ms), involuntary, jerky movement that may arise from sudden muscle contractions (ie, positive myoclonus) (▶ Video 13.1) or sudden interruption of ongoing muscle contractions with resultant postural lapses (ie, negative myoclonus or asterixis). In asterixis, when the hands are examined extended in front of the patient with the wrists maximally extended, the brief flapping of the outstretched arms is due to transient relaxation of the muscles that maintain posture of those extremities. Asterixis is usually due to metabolic abnormalities.

Myoclonus can appear when the affected body part is at rest, but it may also occur when it is performing a voluntary motor act (ie, "action myoclonus"). Myoclonic jerks are usually arrhythmic but can also be rhythmic (such as in *myorhythmia*).

Dystonia

Dystonia (see Chapter 79) is an involuntary movement of sustained muscle contraction that frequently causes twisting or abnormal postures. The spasms may affect the neck muscles (*cervical dystonia*) (▶ Video 13.2), periocular muscles (*blepharospasm*), facial muscles (*Meige syndrome*), vocal cords (*spasmodic dysphonia*), or limb muscles (eg, *writer's cramp*). At the muscular level, dystonia is characterized by sustained cocontractions of agonist and antagonist muscles simultaneously, resulting in muscles combatting each other and the generally slow development of an abnormal posture. Voluntary movements may be opposed by contractions of muscles that are inappropriate to the task (*action dystonia*).

Several additional features may be present, including (1) an increase of these involuntary contractions when voluntary movement in other body parts is attempted ("overflow"); (2) interruptions of these involuntary, sustained contractions with jerky oscillatory movements that appear tremor-like (*dystonic tremor*); (3) the presence of a "sensory trick" or *geste antagoniste*, which is when the dystonic movements can be diminished by tactile or proprioceptive inputs, such as lightly touching the involved or an adjacent body part (eg, touching the chin in cervical dystonia); and (4) the emergence of the dystonic movements only during certain actions such as writing or playing a musical instrument (*task specificity*). Inexperienced clinicians might assume that some of these features point to a psychogenic origin of the symptoms, but in reality, the presence of these features is classic for organic dystonia.

TABLE 13.2 Explanation of Descriptive Terms for Involuntary Movements by Category

Category	Descriptive Term	Explanation	Example Phenomenology
Voluntariness	Voluntary	Completely within the control of the patient	Lifting a cup to drink
	Semivoluntary	Partially within the control of the patient; may be suppressed if even temporarily; may be associated with an uncontrollable urge to move and relief after movement	Akathisia
	Involuntary	Completely outside of the patient's control; insuppressible	Myoclonus
Rhythmicity	Rhythmic	Occurring at a regular frequency	Tremor
	Arrhythmic	Occurring at an irregular frequency	Dystonia
Pattern	Stereotyped	Patterned and somewhat predictable	Tics
	Nonstereotyped	Unpatterned and unpredictable	Chorea
Texture	Oscillatory	Consisting of alternating agonist and antagonist muscle activity rotating around a central plane or axis	Tremor
	Jerky	Brief and unilaterally directed	Myoclonus
	Flowing	Appearing to continuously move from one body part to another	Chorea
	Sustained	Consisting of prolonged muscle contractions	Dystonia
	Ballistic	Large amplitude	Ballism

TABLE 13.3 List of Hyperkinetic Phenomenologies With Descriptive Terms

Phenomenology	Descriptors
Myoclonus	Involuntary, jerky
Dystonia	Involuntary, sustained
Chorea	Involuntary, nonstereotyped, flowing
Athetosis	Involuntary, nonstereotyped, flowing
Ballism	Involuntary, nonstereotyped, ballistic
Tics	Semivoluntary, stereotyped
Stereotypies	Semivoluntary, stereotyped
Tremor	Involuntary, rhythmic, oscillatory
Akathisia	Semivoluntary, stereotyped or nonstereotyped, flowing

Chorea/athetosis
Ballism
Low amplitude>>>

FIGURE 13.5 Flowsheet of types of tremor.

whether the tremor is present during different conditions: when the affected body part is at rest (rest tremor), as in parkinsonian disorders, or when the affected body part is being used (action tremor) (Fig. 13.5). There are several types of action tremor: (1) postural tremor—present when an antigravity posture is maintained (eg, with arms outstretched in front of the body or with elbows flexed with arms in a winged position), as in essential tremor and Wilson disease (see Chapters 76 and 139); (2) kinetic tremor—occurring when action is undertaken (eg, writing or pouring water from a cup) (▶ Video 13.5), as in essential tremor; (3) intention tremor—present when approaching a target (eg, during finger-to-nose maneuver), as in diseases involving the cerebellum such as ataxias and essential tremor (see Chapters 76 and 82); and (4) isometric tremor—occurring with sustained muscle contraction against a stationary object (eg, when making a fist or carrying a shopping bag).

Akathisia

Akathisia is a semivoluntary, stereotyped or nonstereotyped, flowing movement. Much like in tics—which are also semivoluntary—patients with akathisia report an urge to move, manifesting as an inner feeling of profound restlessness (▶ Video 13.6). Movements may be stereotyped, such as rocking or pacing, or nonstereotyped, appearing simply as jitteriness or restlessness. Akathisia is most commonly seen as a side effect of medications with dopamine-blocking properties (eg, antipsychotics, antiemetics), either as acute akathisia or tardive akathisia (after prolonged treatment), the latter of which often accompanies tardive dyskinesia. Stimulants may also induce akathisia. In addition to that induced by medications, pathologic akathisia may be seen in the encephalopathies of confusional states, in some dementias, and in Parkinson disease. Picking at the bedclothes (ie, carphology) is a manifestation of akathitic movements in patients who are bedridden. Akathitic movements may also be a reaction to stress, anxiety, boredom, or impatience, such as when a person shakes his or her leg up and down while seated in a chair; these may then be termed *physiologic akathisia*.

Other Hyperkinetic Movements With Variable Phenomenologic Features

Dyskinesias

Dyskinesias are abnormal involuntary movements that do not cleanly fit into a phenomenologic category (▶ Video 13.7). Commonly, dyskinesias are related to medication side effects, such as in levodopa-induced dyskinesia or tardive dyskinesia (see Chapter 83) secondary to dopamine-blocking agents. Dyskinesias may consist of a combination of phenomenologies or may appear similar to a particular phenomenology but differ in an essential way. For example, tardive dyskinesias are often referred to as *choreiform* in that they are involuntary, flowing movements but are commonly more stereotyped than what is characteristic of chorea and can include dystonic features.

Asynergia and Ataxia

Like dyskinesias, *asynergia* or *dyssynergia* do not cleanly categorize into a hyperkinetic phenomenology; rather, they are related to abnormal regulation of voluntary movements, resulting in incoordination. This may manifest as *dysmetria* or *limb ataxia*, such as may be observed in finger-nose-finger or heel-to-shin testing, wherein the limb misses the target with alternating overshooting and undershooting. There may be an associated *intention* (or terminal) *tremor*. *Dysdiadochokinesia*, the breakup and irregularity that occurs when the limb is attempting to carry out rapid alternating movements, is another example of *asynergia*. *Ataxia* of gait is typified by unsteadiness on walking with a wide base, the body swaying, and a difficulty with tandem walking (heel-to-toe walking).

Asynergic disorders may be episodic, static, or progressive. Hypotonia may be present on examination. Such disorders result from cerebellar diseases (see Chapter 82) or lesions involving the pathways to or from the cerebellum.

Hyperekplexia

Hyperekplexia (exaggerated startle) consists of dramatic, complex motor responses to sudden tactile or auditory stimuli. The reaction can consist of a blink; facial contortion; abduction of

the arms; and flexion of the neck, trunk, and arms. Sometimes, instead of movements, the body becomes stiff and immobile. When it is severe, the patient's movements must be curtailed because a sudden attack may lead to injury from falling. The etiology may be hereditary or sporadic.

Functional Involuntary Movements

Functional or psychogenic involuntary movements are highly variable, manifesting as shaking, fixed postures, bizarre gaits, paroxysmal disorders, or other phenomena (**Table 13.4**). Careful evaluation of the phenomenology for inconsistency, incongruity, prolonged fixed postures, deliberate slowness, suggestibility, distractibility, entrainment, false (give-way) weakness, nonanatomic sensory impairment, and marked fatigue and exhaustion from the movements suggest the diagnosis.

NEUROANATOMY

Most involuntary movements are the result of central nervous system disorders and, more specifically, lesions involving the basal ganglia or cerebellum. For example, the motor features of Parkinson disease are related to a lesion in the substantia nigra pars compacta, chorea is related to disorders of the caudate nucleus but sometimes involving other structures, and ballism is most often related to lesions of the subthalamic nucleus. Ataxia and intention tremor are related to lesions of the cerebellum. Despite central nervous system predominance in movement disorders pathophysiology, abnormal movements attributed to a peripheral etiology do also occur (eg, hemifacial spasm, painful legs–moving toes, jumpy stump).

The neural site of origin of myoclonus spans central and peripheral localizations, including the cerebral cortex (cortical myoclonus), brain stem (reticular reflex myoclonus), spinal cord (propriospinal myoclonus), or peripheral nerve (eg, hemifacial spasm).

TABLE 13.4 Red Flags for Functional/Psychogenic Movements

Finding	Explanation
Inconsistency	Movements that change quality (eg, change in direction or frequency)
Combination of several hyperkinesias that do not ordinarily occur together	Unusual combinations of movements that do not typically co-occur in organic disease
Fixed postures	Postures that are sustained for prolonged periods of time
Deliberate slowness	Practiced slowness that resolves when the patient is unaware that they are still being observed
Effortfulness	Patient demonstrates extraordinary effort during tasks that should not be affected (cognitive tasks, tasks with unaffected body parts).
Suggestibility	The movement is reproduced when the examiner performs a maneuver that he or she suggests will acutely bring on the movement.
Distractibility	The movement stops when the examiner draws the patient's attention away from the affected body part to perform a task that requires considerable effort and concentration.
Entrainment (in tremor disorders)	Tremor frequency changes to match the frequency of tapping with the opposite limb.
Give-way weakness	During strength testing, the patient initially provides resistance against the examiner's force but then suddenly "gives way" and provides no further muscular resistance.
Nonanatomic sensory impairment	Sensory deficits that do not follow anatomic patterns/boundaries
Marked fatigue and exhaustion	By history, the amount of fatigue is out of proportion to the severity of the movements.

DIAGNOSIS

The first step in diagnosing a movement disorder is to recognize the movement phenomenology itself, and this is based primarily on keen and unhurried observation. Once the specific movement or movement types are identified, one may consider the various etiologies that can result in that/those type(s) of movements. In some instances, electromyogram may be helpful by determining the rate, rhythmicity, and synchrony of involuntary movements as well as the duration of individual contractions. The duration of an individual contraction may distinguish specific types of involuntary movements; for instance, differentiating an organic myoclonic jerk from a psychogenic one. Motor control physiology laboratories typically perform this service. Additional blood work as well as brain imaging may aid in the diagnosis, although these should not be used as a substitute for clinical observation.

Functional/psychogenic movements are subconscious and thus involuntary, in contrast to malingering. A common mistake is to label an abnormal movement not previously encountered by the physician as functional. Experience of seeing a large number of movement disorders brings knowledge that helps in distinguishing functional versus organic movements. Functional disorders are not simply diagnoses of exclusion, but rather the diagnosis is made based on positive findings on history and examination as outlined in **Table 13.4**.

TREATMENT

The initial management of involuntary movements is the triaging into those that require acute treatment versus those that do not. There are a small number of movement disorders that must be dealt with acutely, including acute dystonic reactions, neuroleptic malignant syndrome, and the paralytic form of Sydenham chorea (**Table 13.5**). A number of emergent situations may arise in the treatment of patients with involuntary movements, including acute psychosis in patients with Parkinson disease and dystonic storm (see **Table 13.5**). The initial management of the remaining patients depends very much on the stage and severity of the disease; in many instances, a realistic goal of therapy is to lessen the frequency, severity, and functional impact of movements rather than to aim for complete cessation. Many patients may not require treatment; it is important to ascertain impact of the abnormal movement on the patient's quality of life to determine if treatment is necessary.

Videos can be found in the companion e-book edition. For a full list of video legends, please see the front matter.

TABLE 13.5 Movement Disorders Emergencies

Entity	Comments	Acute Management
Dystonic storm	Continuous dystonic spasms	• Admission to ICU • Monitor fluids and electrolytes. • Treat rhabdomyolysis. • Treat with anticholinergic agents (diphenhydramine), baclofen, and benzodiazepines (lorazepam). • Sedation, airway protection, and paralysis may be necessary.
Hemiballismus	Continuous violent flailing, lateralized arm and leg movements seen with injury to the subthalamic nucleus	• May require intubation, sedation, and paralysis in the most severe cases
Acute psychosis in patients with Parkinson disease	Generally due to medication effects	• Acute hospitalization may be necessary. • Reduce and/or withdraw medication. • Treat with antipsychotic agents (ideally with low dopamine blockade).
Parkinsonian hyperpyrexia	May occur in a variety of settings including abrupt medication withdrawal, infection	• Admission to ICU • Monitor fluids and electrolytes. • Carbidopa/levodopa, dantrolene, or steroids may be beneficial.
Stridor in patients with multiple system atrophy	More often at night and may result in respiratory arrest	• Nasal continuous positive airway pressure mask • Botulinum toxin injections to the thyroarytenoid muscles • Tracheostomy
Neuroleptic malignant syndrome	Due to drugs with dopamine-blocking activity	• Admission to ICU • Withdrawal of offending medication • Treat with bromocriptine, amantadine, dantrolene, or lorazepam.
Acute dystonic reaction	Due to drugs with dopamine-blocking activity	• Withdraw offending drug. • Treat with IV diphenhydramine.
Oculogyric crisis	Due to drugs with dopamine-blocking activity	• Withdraw or lower dose of offending drug. • Treat with IV diphenhydramine.
Paralytic form of Sydenham chorea	A severe hypotonic state with paralysis	• Treatment with IV steroids

Abbreviations: ICU, intensive care unit; IV, intravenous.

14 Muscle Weakness, Cramps, and Stiffness

Comana M. Cioroiu

KEY POINTS

1. Complaints of true muscle weakness must be distinguished from similar subjective symptoms caused by problems outside of the nervous system.
2. Pathology within the extrapyramidal system (ie, basal ganglia and cerebellum) may cause symptoms of stiffness, clumsiness, or imbalance that may be experienced by the patient as weakness.
3. A detailed history and neurologic exam is crucial to establishing the etiology of the patient's weakness and helps localize it to a particular portion of the central or peripheral nervous system.
4. "Red flag" features such as a rapidly progressive or sudden weakness or associated features such as shortness of breath or incontinence warrant a much more expedited workup.
5. It is important to identify patients in need of prompt evaluation where the most important tests to be ordered often include pulmonary function tests and a formal swallowing evaluation.
6. Pattern recognition is key in localization of a complaint to a particular part (or parts) of the nervous system.
7. Testing should be ordered following a detailed history and examination suggesting the appropriate localization and may include imaging, laboratory studies, and electrodiagnostic tests among others.

INTRODUCTION

Weakness is one of the most common complaints in all of neurology; hence, both the scope of the term and its differential diagnosis is broad. A patient may have weakness due to a lesion anywhere in the central or peripheral nervous system from the motor cortex to the muscle itself. Often, patients will use the term *weakness* to describe various functionally limiting symptoms unrelated to loss of strength as with the bradykinesia seen in parkinsonism or the clumsiness experienced with cerebellar ataxia. The concept of weakness is particularly challenging to differentiate from an overall sense of fatigue or asthenia, which is a common complaint in patients with psychiatric (ie, depression) or systemic diseases such as cancer.

It is not at all uncommon for patients to present to the neurologist with a feeling of poorly described generalized weakness, which can be attributed to various nonneurologic etiologies with no specific neurologic cause. The charge of the neurologist in this situation is to focus on the backbone of our specialty: Obtain a comprehensive history and perform a detailed neurologic examination to determine if the patient's complaints are caused by a problem within the nervous system.

MANAGEMENT STRATEGY

Asking the patient about the specific functional consequences of his or her weakness (ie, trouble climbing stairs, buttoning buttons, opening jars) may help distinguish generalized weakness due to fatigue from weakness with an underlying localizable neurologic cause. Both the history and examination should help the clinician localize the problem to a specific region of the central or peripheral nervous system and give clues to possible etiologies. Symptoms concurrent and associated with the weakness are helpful in formulating a diagnostic impression. Complaints of muscle pain, cramping, or stiffness may invoke a myopathy, whereas numbness or tingling suggests a peripheral neuropathy or central nervous system lesion.

Specific "red flags" in the history or examination may provide important clues and prompt one to institute more acute treatment (Table 14.1). Once a comprehensive differential diagnosis is made, testing is done to confirm or exclude a specific disorder and may include but not be limited to serum studies, imaging, and electrodiagnostic testing. Many weak patients are encountered in the office setting; however, acute weakness may present in the hospital as well and often warrants a more prompt evaluation and rapid institution of therapy (Table 14.2).

NEUROANATOMY AND LOCALIZATION OF WEAKNESS

Weakness can be localized to various regions within the neuraxis, from the cortex to the muscle itself, and can be thought of as originating within either the central or peripheral nervous system.

TABLE 14.1 Red Flags in the Evaluation of Weakness

- Weakness that becomes severe over a few days or less
- Dyspnea
- Inability to raise the head against gravity
- Bulbar symptoms (eg, difficulty chewing, talking, and swallowing)
- Loss of ambulation
- Changes in bowel or bladder function

TABLE 14.2 Key Steps in the Diagnosis and Management of Weakness

- Characterize the weakness in terms of tempo, variability, distribution, and associated symptoms.
- Perform a detailed neurologic examination to help localize the weakness within the neuraxis.
- Determine if there are predominantly upper or lower motor neuron findings.
- Look out for red flags (see Table 14.1).
- Order appropriate tests depending on most likely localization and differential diagnosis.
- Beware of diagnoses or signs prompting acute intervention (ie, Guillain-Barré syndrome, mononeuritis multiplex, or myasthenia gravis).

The central, or pyramidal, motor system is composed of the motor cortex, corticospinal tract, and the various other tracts that modify and interact with it (ie, the rubrospinal and tectospinal tracts). Weakness related to a central process affecting the corticospinal tract or pyramidal system is typically thought to produce a clinical syndrome of upper motor neuron weakness manifested by spastic tone, hyperreflexia, and pathologic reflexes (ie, Babinski response).

Weakness due to pathology in the peripheral nervous system characteristically produces a pattern of peripheral lower motor neuron weakness consisting of hyporeflexia, muscle atrophy and wasting, reduced tone, and in some cases, spontaneous muscle activity such as fasciculations. The peripheral motor system is typically considered to include the motor neuron within the anterior horn of the spinal cord (or brain stem for cranial nerves), the peripheral nerve, neuromuscular junction, and muscle distal to it. Both the history and neurologic exam will help localize the problem to a particular part of the neuraxis and thus guide one's differential diagnosis and treatment plan.

Central (Upper Motor Neuron) Weakness

The corticospinal tract or pyramidal system can be damaged anywhere along its tract from the cortex through the corona radiata to the posterior limb of the internal capsule and down to the brain stem via the cerebral peduncles of the midbrain to the medulla and spinal cord. The highest possible lesion is in the primary motor cortex of the brain, where the largest of the pyramidal cells (Betz cells) lie in layer 5 of the cortex. Responsibility for planning and preparation of movement lies within the supplementary and premotor cortices, which regulate the motor action. The actions of the corticospinal tract are further modulated by the cerebellum as well as the basal ganglia and its tracts, which is also known as the *extrapyramidal system*. Pathology within this system can lead to either a paucity or an exaggeration of movement, and the functional impairment experienced by the patient can be frequently described as weakness.

The neurologic examination and history can point toward a diagnosis localized within either the cerebellar or extrapyramidal system (such as Parkinson disease) and can include such findings as ataxia, bradykinesia (paucity and slowness of movement), tremor, and postural instability. In many cases, the key to localization is "pattern-matching"—actively looking for a pattern or constellation of findings that point to a specific cause of weakness (Table 14.3).

Cortical Lesions

A variety of diseases can affect the corticospinal tract from large strokes or hemorrhages to tumors and infections. Cortical lesions cause a characteristic pattern of weakness, where one limb is typically preferentially affected due to the distribution of motor representation in the homunculus of the primary motor cortex. For instance, infarcts affecting the middle cerebral artery territory will preferentially affect the arm and face more so than the leg. Often, there are other associated cortical signs such as aphasia or neglect, and patients may also present with headaches or seizures. Cortical weakness can also result from etiologies such as atypical migraine or postictal Todd paralysis; these diagnoses should be considered in the appropriate clinical setting.

Subcortical Lesions

Subcortical lesions, such as those in the internal capsule, will present with more complete unilateral weakness that may or may not spare the face. Demyelinating diseases such as multiple sclerosis (MS) are often implicated in subcortical weakness, although various other etiologies such as infarct or tumor are possible as well. Weakness attributed to a brain stem lesion can present with unilateral weakness of an arm and leg, and the face may be involved as well. There are usually associated symptoms attributable to cranial nerve dysfunction such as diplopia and facial numbness or hemiataxia due to involvement of cerebellar tracts within the brain stem.

Spinal Cord Lesions

After decussating in the pyramids of the medulla, the lateral corticospinal tract is formed within the spinal cord where it travels ipsilateral to the innervated side of the body, lying anterior to the posterior columns and medial to the posterior spinocerebellar tract. Of note, about 10% of fibers in the corticospinal tract do not decussate and travel down into the cord to form the anterior or ventral corticospinal tract. Patients with weakness related

TABLE 14.3 Common Etiologies of Weakness Depending on Time Course

Acute (Seconds to Minutes)	Subacute (Minutes to Hours)	Chronic (Months to Years)
• Infarction • Hemorrhage • Periodic paralysis • Complicated migraine • Trauma • Postictal Todd paralysis • Conversion disorder	• Demyelinating CNS disease (ie, MS) • Toxic ingestion • Plexopathy • Acute demyelinating neuropathy (Guillain-Barré syndrome) • Metabolic disturbances • Neuromuscular junction disease • Infection • Mononeuritis multiplex	• Neoplasm • Neuromuscular junction disorder • Axonal polyneuropathy • Structural lesion (ie, herniated disk) • Motor neuron disease • Myopathy

Abbreviations: CNS, central nervous system; MS, multiple sclerosis.

FIGURE 14.1 Brachial plexus. (Adapted from Marshall R, Mayer S. *On Call Neurology*. 3rd ed. Philadelphia, PA: Saunders; 2007.)

to spinal cord pathology will typically present with both motor and sensory complaints, which can be bilateral or localized to one limb. Pain may be present or absent, and its description will vary depending on the cause of weakness. For instance, it may be described as stiffness related to myelopathy, Lhermitte sign (shock-like sensations with back flexion), or diffuse back pain. There may be disturbances in bowel or bladder function requiring prompt evaluation for cord compression.

Peripheral (Lower Motor Neuron) Weakness

Upper motor neurons that form the corticospinal tracts synapse with both interneurons and lower motor neurons within the anterior horn of the spinal cord. The motor unit is defined as one α-motor neuron within the anterior horn (or brain stem when related to cranial nerves) and all of the muscle fibers it innervates. Pathology within the anterior horn itself may present with a combination of both upper and lower motor neuron signs as seen in amyotrophic lateral sclerosis and often includes concomitant bulbar weakness. Patients with weakness localized to the anterior horn will often present with asymmetric weakness, which begins in the bulbar region or within one limb and then progresses segmentally over time. Pain related to muscle cramps and stiffness is a common complaint.

The lower motor neuron exits the spinal cord to form the ventral motor portion of the spinal nerve root, after which it meets the dorsal sensory nerve root past the dorsal root ganglion to form the peripheral nerve. At this location, the dorsal nerve root is commonly susceptible to compression by vertebral disk herniation, and patients may present with radiating pain or sensory loss corresponding to a particular *dermatome*. A *myotome* is defined as the group of muscles innervated by one single nerve root. Most muscles are supplied by two or more nerve roots, and thus a single root lesion rarely causes marked weakness due to this overlap within myotomes.

Brachial Plexus

Prior to separating into specific peripheral nerves, the motor and sensory fibers together form a network called a *plexus*, of which there are two (brachial and lumbosacral). The brachial plexus consists of nerve roots from C5 to T1, whereas the lumbosacral plexus consists of those from L1 to S3. The brachial plexus is composed of three trunks (upper, middle, lower) dividing into two divisions (anterior and posterior), which then form three cords (medial, lateral, posterior) ultimately subdividing and ending in terminal peripheral nerves (Fig. 14.1). Different peripheral nerves come off the brachial plexus at different levels; some, such as the phrenic nerve, exit immediately off the nerve roots, whereas others form the terminal branches of the plexus. These terminal nerves may be pure motor, pure sensory, or mixed.

Lumbosacral Plexus

The lumbosacral plexus is arranged somewhat differently, with various nerve roots coming together to form large nerves that then continue to differentiate into terminal branches or peripheral nerves. For instance, nerve roots from L4 to S3 come together to form the sciatic nerve, which later then subdivides into the fibular and tibial nerves. Weakness localized to the plexus typically presents with acute or subacute pain in one limb and is most commonly traumatic but can also result from other various etiologies such as infectious, structural, and inflammatory causes. Weakness is localized to one limb, often in the distribution of various nerves. There may be associated sensory complaints, but the sensory examination is frequently normal.

Peripheral Nerves

Terminal or peripheral nerves may be affected in isolation (mononeuropathy) or together in a uniform or multifocal pattern. Mononeuropathies are most commonly due to compression, and symptoms and exam findings are restricted to the distribution of one nerve distal to the injury. Polyneuropathies have a broad

FIGURE 14.2 Patterns of sensory loss in patients with neuropathy. A: Polyneuropathy: diffuse stocking-glove pattern. B: Mononeuropathy: focal involvement corresponding to a single peripheral nerve. C: Mononeuritis multiplex: pattern of multiple, asymmetric regions of sensory loss corresponding to multiple peripheral nerves. (Adapted from Marshall R, Mayer S. *On Call Neurology*. 3rd ed. Philadelphia, PA: Saunders; 2007.)

differential and can be subdivided into those caused by demyelination and those with predominant axonal involvement.

Demyelinating neuropathies typically also involve the nerve roots and can be referred to as *radiculoneuropathies*. They tend to have a motor greater than sensory predominance, present with more generalized or multifocal rather than length-dependent weakness, and areflexia is typical on examination. Cranial nerves may be affected as well.

Axonal polyneuropathies are usually length-dependent, affect sensory greater than motor function, and spare cranial nerves. The differential for such a polyneuropathy is vast and includes metabolic, infectious, and systemic causes among others. Diabetic neuropathy is by far the most common etiology of length-dependent axonal polyneuropathy.

At times, different peripheral nerves can be affected in an asymmetric and patchy fashion (Fig. 14.2). Such a syndrome of multiple mononeuropathies (also frequently referred to as *mononeuritis multiplex*) is often the result of ischemic injury to different peripheral nerves and present with acute and painful weakness and sensory loss. In these instances, it is crucial to rule out an underlying vasculitis because management must be prompt to avoid further irreversible injury.

Neuromuscular Junction

Each peripheral nerve ultimately terminates at the motor endplate of the muscle it supplies, where it forms the neuromuscular junction. At this point, calcium influx into the terminal portion of the neuron leads to binding of acetylcholine-containing vesicles to the neuronal membrane and release of acetylcholine into the postsynaptic space. The acetylcholine-release site is known as the *active zone* and is the location of both calcium influx via voltage-gated calcium channels and acetylcholine release. Binding of acetylcholine to its corresponding postsynaptic receptors at the motor endplate leads to opening of sodium channels and consequent depolarization of the muscle membrane and an endplate potential. The summation of several endplate potentials is ultimately what leads to a discrete muscle fiber potential and subsequent muscle contraction.

Weakness localized to the neuromuscular junction (see Chapter 93) often presents with proximal and bulbar weakness, which fluctuates with activity and time of day. Autoantibodies may be directed toward components of the presynaptic membrane (ie, toward the voltage-gated calcium channel in Lambert-Eaton myasthenic syndrome) or the postsynaptic membrane (ie, myasthenia gravis, where antibodies are formed against acetylcholine receptors). The muscle fiber action potential causes depolarization of the internal portion of the muscle fiber and leads to activation of calcium channels in the sarcoplasmic reticulum of the myocyte leading to calcium release. Calcium then binds to troponin C on the actin filaments of the myofibril, thereby unbinding tropomyosin from the filament, allowing the binding of myosin. The binding of adenosine triphosphate to myosin then allows unbinding and release of actin, thereby leading to muscle relaxation.

Myopathy

Muscle weakness due to pathology within the muscle itself is frequently proximal, symmetric, and progressive. There can be associated facial weakness and weakness of eye movements (such as in mitochondrial myopathies). Myalgias are common, and the sensory examination should be normal. Etiologies are variable and can include inflammatory, congenital, and metabolic causes.

FOCUSED HISTORY

Demographics and Past Medical History

Knowledge of the patient's age and prior medical history is crucial because various etiologies are more or less likely depending on the age of the patient. A left hemiparesis presenting in a young woman is more likely to be attributable to an MS flare than a stroke, and the opposite is true in an 87-year-old man with hypertension.

One must be careful to obtain a complete list of medications the patient is taking because certain exposures may provide diagnostic clues (ie, statin myopathy). The social history is important to obtain, particularly with respect to toxic exposures and travel because both toxic ingestion (ie, alcohol, lead) and various infectious agents may lead to weakness of either central or peripheral origin. A detailed family history is required in cases of suspected hereditary disorders and a pedigree is often helpful. Thus, the age and complete medical, social, and family history of a patient will help formulate an appropriate differential diagnosis based on likelihood and help dictate management.

Tempo of Weakness

One of the key questions one must ask is the time of onset and whether the weakness is acute, subacute, or chronically progressive (see Table 14.3). Focal weakness that begins abruptly (ie, over seconds to minutes) is most concerning for a vascular event such as a hemorrhage or infarct, and these patients must be emergently assessed and evaluated. Subacute onset of weakness has a broader differential and may be due to demyelinating disease such as MS, a mass lesion, or an acute demyelinating neuropathy, among others. Weakness that evolves chronically

over months to years is suggestive of a neurodegenerative disease such as motor neuron disease, peripheral neuropathy, myopathy, or a slowly progressive structural lesion. *The tempo of the course of symptoms dictates the urgency with which the patient should be evaluated and managed.*

Variability of Weakness

Another crucial component of a detailed neurologic history includes asking about the nature of the weakness and whether it is transient, fluctuating, or permanent. Transient weakness that fluctuates with the time of day or with exertion may point toward a neuromuscular junction disorder, MS flare, or a channelopathy (ie, periodic paralysis).

Distribution of Weakness

The distribution and symmetry of weakness is equally important to characterize when formulating a plan for localization and likely etiology. Weakness affecting one arm and leg on the same side is referred to as *hemiparesis*. If the arm and leg are affected on opposite sides, this is known as *crossed hemiparesis*. If the weakness involves only one limb, this is called *monoparesis*, whereas weakness of both legs is known as *paraparesis*. The term *plegia* in the same context refers to complete paralysis.

Certain patterns of weakness give clues regarding localization. Predominantly upper motor neuron weakness of one limb, with or without facial involvement, suggests a cortical lesion in the central nervous system such as a stroke or MS. Given the distribution of the motor homunculus, incomplete upper motor neuron weakness in one limb suggests a lesion in the cortex, whereas complete hemiplegia involving the face is more likely to be localized to subcortical structures or the brain stem. If certain muscles within one limb (corresponding to a particular myotome or peripheral nerve) are preferentially affected, this may indicate a problem in the peripheral nervous system such as a radiculopathy or mononeuropathy. Generalized weakness can involve all four limbs and be related to a process within the spinal cord (ie, cervical myelopathy), peripheral nerve (ie, polyneuropathy), neuromuscular junction, or muscle.

Further characterizing the pattern as being *distal* or *proximal* is also helpful. For instance, generalized weakness that is symmetric and distal is commonly related to a polyneuropathy, whereas proximal weakness is more likely referable to a problem in the neuromuscular junction or muscle.

Sensory Symptoms

Asking about associated symptoms is crucial to determining not only proper localization but also in assisting with thinking of possible etiologies (Table 14.4). One must ask about associated sensory symptoms because this could point toward a neuropathy, plexopathy, or spinal cord lesion. Sensory disturbances can have a positive quality (tingling, paresthesias, pain) or a negative quality (numbness or loss of sensation). A specific sensory level is indicative of pathology within the spinal cord and should be looked for in the appropriate setting.

Cognitive complaints or language symptoms will always be most suspicious of a cortical process, and weakness in this instance may involve the face and typically affect one limb more than another.

Pain

Pain can be encountered in the setting of neuromuscular weakness but must be differentiated from the diffuse myalgias that can be related to an underlying systemic medical illness or psychiatric disease. Often, this distinction is difficult to make because complaints can be nearly identical. Patients with neuropathy often present with burning pain, which is distal and symmetric, and those with radiculopathy or plexopathy may complain of radiating neck, arm, or shoulder pain. Hand pain is a common manifestation of carpal tunnel syndrome, which may eventually progress to hand weakness and clumsiness. Mononeuritis multiplex due to nerve infarcts in the setting of vasculitis can present with acute pain in a variable distribution. Plexopathy is often heralded by acute to subacute pain in the affected limb prior to weakness or sensory complaints. Weakness in the setting of a slowly progressive brain or spinal cord mass may present associated with headaches or back pain.

Stiffness and Cramps

Muscle stiffness is commonly encountered in upper motor neuron lesions causing spasticity and can be seen in both weakness due to cortical, subcortical, and brain stem lesions as well as with myelopathy in spinal cord syndromes. *Cramps* (a localized muscle spasm or persistent contraction) are more of a lower motor neuron/muscle phenomenon and are encountered frequently in various peripheral syndromes. It is seen as a frequent manifestation of motor neuron disease, where patients may complain of frequent cramps and intermittent debilitating muscle spasms. Those with polyneuropathy may often also have cramping or stiffness that is more constant and less paroxysmal.

Various primary muscle diseases include cramps as a primary symptom, and often, the distinction must be made between cramps and more diffuse myalgias. Myopathies characterized by *myotonia* (prolonged muscle contraction after voluntary contraction or percussion) such as myotonic dystrophy and certain channelopathies commonly present with cramps as an initial symptom. Metabolic and certain mitochondrial myopathies often also may present with intermittent cramps. *Stiff person syndrome* (see Chapter 98) is an autoimmune disorder characterized by painful muscle spasms caused by diffuse or localized body stiffness usually in the absence of weakness.

Visual and Speech Disturbances

If visual complaints are present, it is necessary to characterize them well. A visual field cut or gaze preference may point to a cortical problem, whereas ptosis or diplopia could be a manifestation of a neuromuscular junction disorder or a myopathy.

Trouble with speech in the form of dysarthria must first be differentiated from a language disturbance. The presence of dysarthria may point toward bulbar weakness of various etiologies. A cortical, subcortical, or brain stem lesion may affect tongue fibers; motor neuron disease may present with or lead to bulbar involvement; and similarly, a neuromuscular junction or muscle disorder may involve trouble with speech and swallowing. A complaint of dysarthria should always prompt one to inquire about swallowing difficulties because this may have important management and prognostic implications.

TABLE 14.4 Symptoms Associated With Various Weakness Syndromes

	Cortex	Brain Stem	Spinal Cord	Motor Neuron	Nerve Root or Plexus	Peripheral Nerve	Neuromuscular Junction	Muscle
Sensory loss	May be in the same distribution of weakness (ie, stroke, MS plaque)	May be in the same distribution of weakness	Corresponds to level of weakness, usually with sensory level	*Absent*	Can be in a dermatomal or peripheral nerve distribution	May be in the distribution of one nerve or many nerves (ie, distal stocking-glove distribution)	*Absent*	*Absent*
Cognitive or language deficits	Present	*Absent*	*Absent*	*Absent* (Advanced ALS can be associated with cognitive deficits.)	*Absent*	*Absent*	*Absent*	*Absent*
Pain	Headache may be present.	Headache may be present.	Localized or diffuse back pain	*Absent*	Radicular pain or diffuse pain with plexopathy in the affected limb	Burning or paresthesias (ie, polyneuropathy), acute pain (ie, mononeuritis multiplex)	*Absent*	Myalgias, proximal greater than distal
Cramps or stiffness	Spasticity	Spasticity	Spasticity	Both cramps and stiffness are common.	*Absent*	Both cramps and stiffness with both polyneuropathy and certain mononeuropathies	*Absent*	Cramps common in • Myotonic dystrophy • Channelopathies • Metabolic myopathies • Mitochondrial myopathies • Stiff person syndrome
Visual changes	Involvement of frontal eye fields or hemianopsia	Diplopia or nystagmus	*Absent*	*Absent*	*Absent*	Ophthalmoparesis or diplopia can be seen in GBS or Miller-Fisher syndrome.	Diplopia or ptosis occurs with myasthenia gravis.	Diplopia as can be seen in mitochondrial myopathies, among others.
Speech or swallowing difficulties	Due to tongue/facial weakness	Due to tongue/facial weakness	*Absent*	Bulbar involvement in motor neuron disease	*Absent*	Can be seen in demyelinating neuropathies with cranial nerve involvement	Nasal speech, dysphagia in myasthenia gravis	Due to both pharyngeal and tongue weakness
Respiratory compromise	Occurs with large infarcts or hemorrhages	Occurs with infarcts or hemorrhages	Can be present with high cervical lesions	Bulbar involvement in motor neuron disease	Phrenic involvement in plexopathies	Can be seen in demyelinating neuropathies with bulbar and phrenic nerve involvement	Bulbar involvement in both pre- and postsynaptic neuromuscular junction disorders	Can be present in certain myopathies (ie, amyloid, distal myopathy with early respiratory failure)
Cardiac symptoms	*Absent*	*Absent*	*Absent*	*Absent*	*Absent*	*Absent*	*Absent*	Cardiomyopathy can be associated with various myopathies (ie, myotonic dystrophy, Duchenne or Becker myopathy).
Urinary disturbances	Incontinence with paracentral frontal lesions	*Absent*	Urinary incontinence with cord compression	*Absent*	*Absent*	*Absent*	*Absent*	Myoglobinuria with certain myopathies (ie, McArdle disease)

Abbreviations: ALS, amyotrophic lateral sclerosis; GBS, Guillain-Barré syndrome; MS, multiple sclerosis.

Respiratory Symptoms

Asking about respiratory involvement is also essential in patients presenting with weakness whether localized or general. Large cortical and brain stem lesions may rapidly lead to respiratory failure when acute. Disorders of the motor neuron, neuromuscular junction, and muscle may often be complicated by respiratory insufficiency, which may present as shortness of breath, early morning headaches, or daytime fatigue. Acute inflammatory demyelinating polyneuropathy at times may lead to diaphragmatic weakness and subsequent respiratory failure, and thus, respiratory function must be carefully monitored in these patients.

Autonomic Disturbances

Urinary complaints (most often incontinence or frequency) are most commonly seen with upper motor neuron lesions, such as those involving the paracentral frontal lobe or spinal cord. A complaint of dark-colored urine may indicate the presence of myoglobinuria indicative of muscle breakdown suggesting a primary muscle disease such as McArdle disease. One should ask about autonomic involvement as well (ie, symptoms of orthostasis, dry mouth or eyes) because this may play an important role in certain neuropathies. Finally, symptoms suggesting cardiac involvement such as syncope, chest pain, and shortness of breath with activity may be worrisome for a concurrent cardiomyopathy as can be seen with certain myopathies (ie, Duchenne or Becker muscular dystrophy).

FOCUSED EXAM

A focused and goal-directed neurologic exam is critical to the evaluation of a patient with weakness. Ideally, this should be done with the patient undressed and in a gown. Acquisition of both supine and standing heart rate and blood pressure, when appropriate, is useful to assess for orthostatic changes suggestive of autonomic nervous system involvement.

Mental Status

Testing of mental status is important, particularly in cases of weakness due to cortical and subcortical processes (ie, stroke, neoplasm) because this may further assist in localization. Weakness due to a peripheral nervous system disorder should be accompanied by preserved cognitive and language function.

Cranial Nerves

In testing cranial nerves, particular attention should be paid to examination of the eyes starting with their appearance at rest. One should make note of the presence or absence of ptosis, skew, or other asymmetry at rest. Both central and peripheral processes may lead to pupillary involvement with or without ophthalmoparesis.

A careful assessment of extraocular movements is essential because they can be abnormal in states affecting supranuclear, nuclear, and peripheral cranial nerve function (ie, brain stem processes) as well as in diseases of the neuromuscular junction (ie, myasthenia gravis) and muscle (ie, mitochondrial myopathies).

Facial strength is examined both by assessment of asymmetry at rest (ie, a flattened nasolabial fold) as well as by having the patient activate various muscles. Ask the patient to forcefully close his or her eyes and subsequently try to pry them open to assess strength of eye closure. Patients with facial weakness are typically unable to bury their eyelashes with forced eye closure, and eyes are easily pried open. To assess strength in the lower face, ask the patient to purse his or her lips together or whistle. Asymmetric facial weakness sparing the forehead implicates an upper motor neuron facial nerve lesion, whereas facial weakness involving the entire half of the face suggests a peripheral seventh cranial nerve lesion. Symmetric weakness of the facial muscles most typically implies a lesion of the neuromuscular junction or muscle but can rarely also be seen in certain demyelinating neuropathies and in motor neuron disease with bulbar involvement.

Tongue weakness can be evaluated by looking for deviation with tongue protrusion and by having the patient push the tongue against the inner cheek with the examiner's resistance. The tongue should also be carefully inspected for the presence of atrophy and fasciculations as can be seen with motor neuron disease. Pharyngeal weakness should also be assessed by having the patient make guttural sounds and checking for the presence of an intact gag reflex.

Motor Examination

Inspection

The motor examination should always begin with inspection and observation. It is in this part of the examination that one makes the distinction between weakness due to upper motor neuron dysfunction (most commonly related to a process localized to the corticospinal tract) versus lower motor neuron disease localized to the peripheral nervous system. One should look for muscle atrophy and wasting, both in large proximal muscles as well as in the smaller distal muscles such as the intrinsic hand muscles (ie, first dorsal interosseous) in which subtle atrophy can often be more frequently appreciated.

Adventitious Movements

Abnormal movements such as *fasciculations*, *myokymia*, and *tremor* should be sought in various muscles. The presence of atrophy and fasciculations are indicative of lower motor neuron dysfunction as can be seen with motor neuron disease or chronic mono- or polyneuropathies. Myokymia can be seen not only in limb muscles but also in the face, where it typically is suggestive of a brain stem lesion such as an MS plaque. The back should also be inspected for both atrophy (ie, scapular winging) as well as fasciculations.

Tone

Increased tone in the arms can manifest as either rigidity (resistance that is consistent and present throughout the full range of motion) related to basal ganglia dysfunction or spasticity (resistance that is velocity dependent) related to corticospinal tract disease and upper motor neuron dysfunction. When testing tone in the arms, it is often helpful to have the patient open and close the opposite hand, which may accentuate mildly increased tone. Examining tone in the legs is often best done in the supine position where the knees are grasped and quickly pulled up. An unintentional lifting of the heels off the bed is indicative of increased tone in the legs, whereas the heels will naturally slide up the bed in the setting of normal tone.

The motor exam is also an appropriate time to check for the presence or absence of *myotonia* when clinically suspected. One approach is to test for grip myotonia by having the patient squeeze the examiner's hand for 10 seconds and then asking the

patient to quickly let go. In the presence of myotonia, the patient will be unable to relax his/her grip quickly. Similarly, one can check for percussion myotonia by tapping on a muscle—those with myotonia will demonstrate subsequent prolonged muscle contraction (typically, the abductor pollicis brevis is used, but the tongue can be checked as well).

Power

Assessment of strength can be done both by objectively examining different muscle groups and by observation. The first step in examination of strength is often testing of *pronator drift* where the arms are outstretched with the palms up and the patient's eyes closed. Those with subtle or overt hemiparesis due to an upper motor neuron lesion will exhibit pronation and a downward drift. Testing of *rapid finger taps* and *arm rolling* may also demonstrate subtle weakness in the setting of a mild hemiparesis. Particularly in cases of suspected peripheral causes of weakness, a detailed examination of various muscle groups is necessary. One must remember to test strength of neck flexion and extension because this may have important implications particularly in motor neuron disease, neuromuscular junction disorders, and myopathies. Strength of neck flexion is often correlated with respiratory insufficiency due to respiratory muscle weakness and is important to check in all cases of motor neuron disease, neuromuscular junction disease, myopathy, and acute inflammatory demyelinating polyneuropathy.

Objective testing of muscle power is traditionally based on the Medical Research Council scale from 0 to 5, with 5 representing full strength and 0 being complete absence of muscle movement. A score of 1 implies a discernable muscle twitch without movement of a full muscle. A score of 2 indicates movement in the same plane of gravity, whereas movement against gravity but not resistance is a score of 3. A score of 4 represents active movement against resistance and can be further assigned a "+" or a "−" when appropriate to make a more subtle distinction between variations in resistance.

When testing power, each muscle should be tested in a position in which it is at its maximal mechanical advantage—for instance, finger abduction should be tested with the wrist in the neutral position and not flexed. At times, weakness may be too subtle to detect with formal testing of power. It is helpful at times to ask the patient to perform certain functional movements, which may be impaired in cases of subtle weakness. For instance, someone with full strength on testing of power may have trouble standing up from a squatted position or hopping on one foot. A recognition and identification of a specific pattern of weakness is important because different diseases will manifest with different patterns of weakness. For instance, weakness in one limb following a specific myotome may point toward a root or plexus problem, whereas symmetric proximal weakness may suggest either a neuromuscular junction or muscle disorder. Knowledge of the innervation and action of various muscle groups are essential in localization of weakness due to a peripheral cause because the pattern of muscle involvement may point one toward a particular localization and diagnosis (Table 14.5).

Sensory Examination

Evaluation of sensory loss is often challenging because it is the most subjective and thus least reliable portion of the neurologic exam. The best approach is to use the sensory exam to confirm what is clinically suspected. Look for particular patterns of sensory loss to complement the clinical picture, such as sensory loss in a dermatomal pattern consistent with a mononeuropathy or in a distal and symmetric pattern consistent with a polyneuropathy. Testing of different modalities is often helpful in discerning specific spinal cord syndromes (ie, Brown-Séquard syndrome) and in distinguishing a large- from a small-fiber neuropathy.

Reflexes

The absence of reflexes or hypoactive reflexes point toward a lower motor neuron lesion in the peripheral nervous system, whereas pathologically hyperactive reflexes, particularly when in the presence of a Babinski sign or Hoffmann sign, are indicative of an upper motor neuron lesion and corticospinal tract localization. Examination of reflexes may be an important diagnostic clue; for instance, complete loss of reflexes in the setting of subacute weakness should prompt one to quickly consider a diagnosis of acute inflammatory demyelinating neuropathy.

Coordination

Tests of coordination such as finger-to-nose testing are often impaired in the setting of weakness, and the distinction should be made accordingly to avoid confusing subtle weakness for cerebellar or sensory ataxia.

Gait

Examination of gait is often critical because the scissoring, spastic gait of myelopathy will look appreciably different from the waddling gait of myopathy with proximal leg weakness. When assessing gait, one can also notice subtle steppage related to a footdrop or circumduction in the setting of a hemiparesis. It is important to differentiate gait disturbance due to weakness from that related to basal ganglia dysfunction as seen with a shuffling, stooped parkinsonian gait or cerebellar disease where a wide-based ataxic gait is the predominant manifestation. More subtle gait testing involving heel, toe, and tandem gait is often sometimes necessary to further complement the rest of the examination and help elucidate the problem.

DIAGNOSIS AND INITIAL TREATMENT

Once one has formed a differential diagnosis based on likelihood of a particular diagnosis (Table 14.6), various tests can be ordered to further confirm or refute one's diagnostic impression. The urgency of certain tests will depend on the clinical context and circumstances. Patients seen in an emergency room or inpatient setting with acute complaints will often require a more prompt evaluation, and tests can be performed on a more urgent basis. Most patients in the office can be managed with tests ordered on an outpatient basis. However, at times, patients can be seen in the outpatient setting that need urgent evaluation, and it is crucial for the clinician to make this distinction following a detailed history and examination.

Recognition of Emergent Situations

A patient presenting to the office with subacute ascending weakness and areflexia should be promptly admitted to the hospital for evaluation and treatment of probable Guillain-Barré syndrome. Similarly, those with chronic weakness and known diagnoses may present with progressive symptoms requiring hospitalization and more urgent management. For instance, a myasthenic presenting

TABLE 14.5 Common Muscle Groups, Actions, and Innervation[a]

Muscle	Peripheral Nerve	Nerve Root	Action
A. Muscles of the Back, Shoulder, and Neck			
Sternocleidomastoid	Spinal accessory	CN XI, C2, C3	Contralateral rotation of the head
Trapezius	Spinal accessory	CN XI, C3, C4	Shoulder elevation
Diaphragm	Phrenic	C3, C4, C5	Inspiration
Serratus anterior	Long thoracic	C5, C6, C7	Protraction and stabilization of scapula
Rhomboid	Dorsal scapular	C4, C5	Abduction and elevation of scapula
Levator scapulae	Dorsal scapular	C4, C5	Elevation of scapula
Supraspinatus	Suprascapular	C5, C6	Abduction of arm to 90 degrees
Infraspinatus	Suprascapular	C5, C6	Lateral arm rotation
Deltoid	Axillary	C5, C6	Abduction of arm past 30 degrees
Teres minor	Axillary	C4, C5	Medial arm rotation
Teres major	Subscapular	C5, C6, C7	Medical rotation and adduction of arm
Latissimus dorsi	Thoracodorsal	C6, C7, C8	Adduction of arm
B. Muscles of the Arm and Hand			
Biceps brachii	Musculocutaneous	C5, C6	Forearm flexion with arm supinated
Brachialis	Musculocutaneous	C5, C6	Forearm flexion with arm pronated
Triceps brachii	Radial	C6, C7, C8	Forearm extension
Brachioradialis	Radial	C6, C7	Forearm flexion with arm supinated to 90 degrees
Extensor carpi radialis	Radial	C6, C7	Hand extension
Supinator	Radial	C6, C7	Forearm supination
Extensor digitorum	Radial (PIN)	C7, C8	Extension of hand and digits two to five
Extensor carpi ulnaris	Radial (PIN)	C7, C8	Hand extension toward ulna
Abductor pollicis longus	Radial (PIN)	C7, C8	Thumb abduction
Extensor pollicis longus and brevis	Radial (PIN)	C7, C8	Thumb extension
Extensor indicis	Radial (PIN)	C7, C8	Index finger extension
Flexor carpi ulnaris	Ulnar	C7, C8, T1	Ulnar hand flexion
Flexor digitorum profundus	Ulnar	C8, T1	Flexion of distal phalanx of digits four and five
Adductor pollicis	Ulnar	C8, T1	Thumb adduction
Abductor digiti minimi	Ulnar	C8, T1	Abduction of fifth digit
Interossei	Ulnar	C8, T1	Finger abduction or adduction
Lumbricals three and four	Ulnar	C8	Flexion of proximal phalanx and extension of distal phalanx of digits four and five
Flexor carpi radialis	Median	C6, C7	Radial hand flexion
Pronator teres	Median	C6, C7	Forearm pronation
Flexor digitorum superficialis	Median	C7, C8, T1	Flexion of the middle phalanx of digits two to five
Abductor pollicis brevis	Median	C8, T1	Abduction of thumb at the metacarpal joint
Flexor pollicis brevis	Median	C8, T1	Flexion of thumb at the metacarpal joint
Opponens pollicis	Median	C8, T1	Thumb opposition
Lumbricals one and two	Median	C8, T1	Flexion of proximal phalanx and extension of distal phalanx of digits two and three
Flexor digitorum profundus	Median (AIN)	C7, C8	Flexion of distal phalanx of digits two and three
Flexor pollicis longus	Median (AIN)	C7, C8	Flexion of distal phalanx of the thumb
Pronator quadratus	Median (AIN)	C8, T1	Forearm pronation

[a]The nerve roots in boldface are the dominant roots involved in that particular muscle's innervation.

with new-onset shortness of breath and dysphagia needs hospitalization for respiratory monitoring and treatment for likely crisis. It is important to identify patients in need of prompt evaluation where the most important tests to be ordered often include pulmonary function tests and a formal swallowing evaluation.

Laboratory Testing

Various tests are available in the evaluation of muscle weakness. Serum studies are important to exclude various metabolic, infectious, inflammatory, or autoimmune conditions. The extent of testing depends on the differential diagnosis. For instance, the workup for causes of axonal polyneuropathy is very broad and can include tests from vitamin levels to heavy metal testing. In cases of suspected neuromuscular junction disease, appropriate antibody testing is necessary, and a creatine kinase should be checked in patients with suspected myopathy.

Genetic tests are now available for those with a family history or other evidence to suggest a congenital or genetic etiology. Imaging is often first line for patients with central causes of weakness.

Imaging Studies

For patients with predominantly upper motor neuron signs and cortical involvement, a computed tomography (CT) scan (see Chapter 21) or magnetic resonance imaging (MRI) (see Chapter 22) of the brain is indicated. Brain imaging is indicated for anyone with a history and exam that localizes to the cortex, subcortex, or brain stem.

In cases of suspected spinal cord pathology, an MRI of the spinal cord is indicated. The exam will guide which particular part of the cord to image because it can be either cervical or thoracic. In some instances, imaging of the lumbosacral spine may also be needed to evaluate the cauda equina and nerve roots. Imaging can also be done of the brachial or lumbosacral plexus, and this is often instructive in cases of plexopathy where trauma, structural lesions, or neoplastic infiltration are suspected. A contrast MRI of the plexus can at times be abnormal in cases of idiopathic brachial neuritis. In patients who cannot tolerate MRI, a CT scan can be helpful to exclude structural and neoplastic processes. A CT myelography is still performed at times in those who cannot undergo MRI and can provide more detailed imaging of the nerve roots than a CT scan alone.

Lumbar Puncture

A lumbar puncture (see Chapter 32) is important to consider in various cases of both central and peripheral weakness. For instance, a patient with a suspected inflammatory, autoimmune, infectious, or neoplastic etiology will typically warrant examination

of the cerebrospinal fluid looking for cells, abnormal protein, and the presence of various other antibodies and cells, which may be diagnostic. It is particularly useful in the diagnosis of Guillain-Barré syndrome where one typically sees a cytoalbuminologic dissociation with elevated protein in the absence of cells.

Electrodiagnostic Testing

Electrodiagnostic testing (see Chapter 26) is important in the evaluation of weakness due to a peripheral cause. Classically, electrodiagnostic testing consisting of nerve conduction studies and electromyography (EMG) have been the standard practice in the diagnosis of several diseases of the peripheral nervous system. These studies are useful for several reasons. First, they can help to localize the problem to the peripheral nerve and exclude other etiologies such as a primary muscle disease, a plexopathy, or a mononeuropathy. Second, it is of crucial importance in helping to distinguish between generalized and focal forms of either purely axonal or demyelinating forms of neuropathy (such as acute or chronic inflammatory demyelinating neuropathy), which may show evidence of markedly slowed conduction velocity or conduction block. Nerve conduction studies and EMG also help assess the severity of the nerve injury partially in demonstrating whether there is resultant denervation of muscle.

Repetitive stimulation testing can be done to evaluate for neuromuscular junction diseases, which may show evidence of electrodecrement or increment. Single-fiber EMG can be done in certain instances because it is the most sensitive (although not specific) test for neuromuscular junction disorders. In cases of motor neuron disease, EMG is necessary to demonstrate diffuse active and chronic denervation of several muscles in various distributions. An EMG is often abnormal in primary muscle diseases and may show evidence of myopathic changes with or without muscle inflammation.

Muscle or Nerve Biopsy

In situations where testing is inconclusive, biopsies can be performed on most tissues in an attempt to make a definitive diagnosis (see Chapter 33). This may include biopsy of brain tissue, the meninges, muscle, or nerve. Given the invasive nature of biopsy, this is typically not performed unless there is a clear need and the benefits of the procedure outweigh the risks.

ACKNOWLEDGMENT

The author would like to acknowledge the work of Dr. Lewis Rowland, who worked on this chapter in the previous edition.

Gait Disorders 15

Ashwini K. Rao

KEY POINTS

1. Gait is a complex task that involves a number of neural networks. It is important to understand the characteristics of gait and the neural control of gait.
2. Disorders of gait are very common in aging and neurologic disorders. Among neurologic disorders, gait impairments are most commonly seen in sensory ataxia, Parkinson disease, hemiparesis, cerebellar ataxia, and frontal cognitive disorders.
3. Falls are a common sequela of gait and balance impairments. It is important to understand the factors (intrinsic and extrinsic) that may influence fall risk.
4. When assessing gait disorders, it is extremely important to obtain a detailed history, medications prescribed, and timeline of onset before conducting standardized assessment of gait and balance.
5. Assessment of gait can be focused by asking a series of questions regarding gait symmetry, pain, bony deformity, step length, step height, support base, pelvic rotation, and joint coordination.

INTRODUCTION

In humans, locomotion enables us to travel greater distances and interact with novel and complex environments. The evolution of bipedal locomotion facilitated the development of complex manipulation skills. The capacity for independent gait is crucial for function: For instance, the loss of independent ambulation is a predictor of the need for long-term care in a number of age-related neurologic disorders. In addition to independent gait, achieving a requisite speed is also important for independent mobility in the community. For example, in people who have suffered a stroke, speed of 0.85 m/s is predictive of the ability to independently ambulate in the community.

The purpose of this chapter is to briefly describe the gait cycle, the neural pathways underlying gait, methods for clinical assessment of gait, and the most commonly seen disorders of gait. Finally, we present the risk factors and assessment of falls in the elderly.

INTRODUCTION TO THE GAIT CYCLE

The gait cycle consists of repetitive sequential movements of the limbs that help propel the body forward along a predetermined line of progression. The gait cycle is defined by foot contact with the ground and extends from the heel strike of one lower limb to the subsequent heel strike of the same limb (Fig. 15.1). We define two phases within each gait cycle: a stance phase, which consists of approximately 60% of the gait cycle, and a swing phase, which consists of approximately 40% of the gait cycle. Stance phase begins with heel strike and ends with toe off and consists of three events—foot flat, midstance, and heel off. The function of the stance phase is to accept the weight of the body on to the supporting (stance) limb. At the beginning of stance (from heel strike to foot flat on the right side) and at the end of stance (from heel off to toe off on the right), both feet are on the ground simultaneously. The period of double

FIGURE 15.1 The gait cycle. The position of the right leg *(shaded red)* shows major events within the gait cycle during stance and swing phases.

TABLE 15.1 Definition of Clinical Gait Measures

Gait Measure	Definition
Speed	Distance covered in unit time (eg, meters per second)
Cadence	Step frequency—number of steps in a given time (steps per minute)
Step length	Distance (measured in meters along the line of progression) between successive heel strikes of the lower limbs
Stride length	Distance (measured in meters along the line of progression) between successive heel strikes of the same limb
Step width	Distance (measured in meters perpendicular to the line of progression) between successive heel strikes of the lower limbs
Step height	Vertical clearance of the foot from the floor during swing
Step symmetry	Ratio of step length on the right and left sides
Step continuity	Ratio of step time on the right and left sides
Foot angle	Angle formed by the long axis of the foot with the line of progression
Walking path	Direction of the line of progression

support comprises approximately 20% of the gait cycle. During midstance, body weight is supported by one limb (single limb support). During a typical gait cycle, the lower limbs move in a symmetric alternating movement with a phase lag of 0.5 (indicating that when one limb initiates swing, the opposite limb is in the middle of stance phase).

The swing phase of a limb begins with toe off and ends with heel strike. The events within the swing phase (foot clearance and midswing) serve to allow the foot to clear the floor as it propels the body forward in preparation for the subsequent step. The events within the gait cycle described earlier pertain to walking at a comfortable preferred speed. As speed of gait increases, the percentage of time spent in double support decreases. During running, there is no double support phase. Gait can be described quantitatively with respect to its spatial and temporal features. Gait measures that can be assessed in the clinical setting are described in Table 15.1 and Figure 15.2.

NEURAL CONTROL OF GAIT

Gait is a complex task that requires the coordinated activity of several brain circuits. Even walking in an uncluttered environment at a preferred speed (considered an easy task) elicits activity in higher cortical regions. The following description briefly discusses the role of different neural circuits in controlling gait. Readers interested in additional details are referred to excellent recent reviews in the Suggested Readings list.

FIGURE 15.2 Spatial characteristics of gait. Spatial gait variables defined by foot placement along the line of progression.

In order to successfully initiate and control gait, the nervous system needs to perform the following tasks:

- Maintain balance against the force of gravity under static (eg, during stance) and dynamic conditions (eg, during walking). Maintenance of balance under dynamic conditions includes predictive and reactive control of destabilizing forces that are either generated internally (eg, destabilizing forces generated by movement of the arms) or externally (eg, destabilizing forces generated by bumping into another person).
- Coordinate movements of the lower limbs to propel the body forward.
- Help navigate complex environments, which may include stationary obstacles (eg, furniture) and moving obstacles (eg, people walking).
- Perform concurrent tasks with walking, such as talking, listening, or manipulating objects (eg, mobile phone).

Most of the experimental work in understanding the neural control of gait has come from experiments with quadruped and biped animals. These experiments suggest that distinct neural circuits perform specific functions. Cortical circuits (including premotor and motor areas, parietal and occipital areas) are involved with activation and guidance. Reciprocal circuits between the cortex-basal ganglia and cortex-cerebellum are involved with regulation of gait (including postural tone, balance, and coordination of limb movement). Finally, brainstem and spinal cord circuits are involved with the execution of gait (including gait initiation, step frequency, reciprocal movements of the lower limbs). A simplified diagram of the neural structures involved in control of gait is presented in Figure 15.3 and functions of brain structures are summarized in Table 15.2.

Activation and Visual Guidance of Gait

Gait can be activated either by a volitional process under the control of cerebral cortical circuits or by emotional cues (fight or flight reaction) under the control of limbic circuits. Volitional guidance of gait requires precise visual information about the environment, which is processed in the visual areas of the occipital cortex. The posterior parietal cortex receives information from the visual cortex and project to the motor areas in the frontal cortex. An important function of the posterior parietal cortex is to construct maps of

FIGURE 15.3 Neural control of gait. Schematic illustration of neural structures involved in the control of gait. Efferent connections are shown in *blue arrows* and afferent connections in *red arrows*. Abbreviations: CPG, central pattern generator; MLR, midbrain locomotor region; PPC, posterior parietal cortex; PPN, pedunculopontine nucleus.

space, which are very important for visual guidance of locomotion. The premotor areas, in particular the supplementary motor area, are important for postural control during gait. The motor cortex projects to interneurons and motor neurons in the spinal cord and is important in the control of limb movements during gait.

TABLE 15.2 Neural Control of Gait

Region	Area	Function
Cortex	Motor areas	Volitional activation
		Visual guidance
	Limbic system	Emotional activation
Subcortical	Basal ganglia	Inhibition of postural tone
		Regulate rhythmic aspects of gait
	Cerebellum	Balance
		Limb coordination
		Adaptation
Brainstem	MLR	Initiation of locomotor pattern
	PPN	Postural muscle tone
Spinal cord	Interneurons	Control locomotor pattern

Abbreviations: MLR, midbrain locomotor region; PPN, pedunculopontine nucleus.

Regulation of Gait

The basal ganglia and cerebellum have a major influence on motor output even though they do not directly project to the motor neurons in the spinal cord. The basal ganglia input nuclei, in particular the putamen, receive inputs from the premotor and motor cortex. The output nuclei of the basal ganglia (globus pallidus internal segment and substantia nigra pars reticulata) project back to the premotor and motor cortex via the thalamus. These projections are thought to be important for regulating movement amplitude and speed. In addition, the basal ganglia send inhibitory projections to the midbrain locomotor region (MLR) and the pedunculopontine nucleus (PPN). The projection from the basal ganglia to the MLR is responsible for regulating the rhythmic aspects of gait. When there is damage to these projections, as seen in Parkinson disease and Huntington disease, rhythmic control of gait is impaired. The projection from the basal ganglia to the PPN is responsible for regulating muscle tone. Damage to these projections leads to disorders of postural muscle tone, as seen in Parkinson disease.

The cerebellum receives a tremendous amount of afferent information from the limbs and vestibular apparatus. In addition, projections from the cerebral cortex to the cerebellum provide information regarding the upcoming movement. The output of the cerebellum is directed to the motor areas of the

cerebral cortex, midbrain (MLR and PPN), and brainstem (vestibular and reticular nuclei). A major function of the cerebellum is to evaluate disparities between intended movement and actual movement (based on feedback). The cerebellum is important for regulating balance and limb coordination during gait and for providing adaptability to novel conditions based on trial and error learning.

Execution of Gait

Two areas in the brainstem are important for initiating and executing locomotion—the MLR and the PPN. The MLR receives inputs from the cerebral cortex, limbic system, basal ganglia, and cerebellum. A primary function of the MLR is activation of spinal cord circuitry to initiate gait. Inputs from the motor areas and the limbic system to MLR provide the neural substrate for activation of gait based on volitional (motor areas) and emotional (limbic system) cues. The PPN also receives inputs from the motor areas of the cerebral cortex, limbic system, basal ganglia, and cerebellum. The PPN inhibits spinal interneurons and motor neurons. A major function of the PPN is to modulate muscle tone during stance and gait. The spinal cord circuitry includes networks of interneurons (central pattern generators) and motor neurons that innervate skeletal muscles. There are two sets of interneurons, termed *half centers*, that project to flexor and extensor motor neurons. The half centers mutually inhibit each other and are responsible for producing the basic locomotor pattern. Although the half centers do not require sensory input to generate the basic locomotor pattern, their activity can be modulated by sensory input from the limbs. For example, signals from proprioceptors of the hip flexors may be used to signal the end of stance phase. In addition, skin afferents from the limbs are important for adjusting stepping movements in the presence of obstacles. Thus, the function of the spinal cord is to execute the rhythmic movement pattern of gait.

EPIDEMIOLOGY OF GAIT DISORDERS

Although it is widely accepted that gait disorders are commonly seen with advancing age and neurologic disorders, their prevalence and incidence are not well understood. The challenge in examining prevalence and incidence is that defining abnormal gait is difficult, partly due to the high variability of typical gait and partly because of unclear standards for classification of gait disorders. For people older than the age of 60 years, about 32% to 36% have gait disorders, of which 16% to 24% are due to neurologic disorders. Among people older than the age of 85 years, approximately 55% report gait impairments. The prevalence of gait disorders is much higher (60%) in people hospitalized with neurologic disorders. The incidence (new cases of gait disorders) of gait disorders due to neurologic disorders is approximately 10% per year.

Among neurologic causes of gait disorders, the most common are sensory ataxia, Parkinson disease, hemiparetic, cerebellar ataxia, and frontal cognitive disorders. Gait impairments can have devastating consequences including falls and injury. Approximately, one-third of community-dwelling individuals older than the age of 65 years fall. Injuries related to falls increase with age. An unfortunate consequence of falls is that individuals often reduce their mobility in order to prevent falls and related incidents. However, reduced mobility further increases risk for falls by reducing muscle strength and worsening balance. In addition, gait disorders increase the risk of institutionalization and death.

FALLS IN THE ELDERLY

Falls are defined as "unexpected events in which a person comes to rest on the floor, ground, or supporting surface." Falls are considered an inevitable consequence of aging and may result in serious adverse events in older adults. Approximately one-third of community-dwelling people older than the age of 65 years fall each year. The number of falls is much higher for older people living in nursing homes: approximately 1.5 falls per bed per year. The high incidence of falls coupled with the susceptibility to injury (because of comorbidities and age-related physiologic changes) leads to adverse events in the elderly. Falls may result in injuries such as abrasions, bruising, lacerations, and sprains. It is important to note that falls resulting in minor injuries may be underreported by patients. A careful ascertainment of history of falls is very important in clinical practice. About 10% of falls result in fractures, the type of fracture depending on the nature of the fall. Forward or backward falls on outstretched hands result in wrist fractures, falls to the side result in hip fractures, and falls resulting in impact to the head may result in head injury and loss of consciousness. Backward falls on the buttocks result in lower rates of fractures, although fractures of the vertebrae can occur.

Falls account for two-thirds of accidental deaths. The other negative consequences of falls include increased fear of falls and reduced mobility. This results in a negative spiral: Reduced mobility leads to reduction in muscle strength, flexibility and postural stability, and gait impairments, all of which, in turn, increase the risk for additional falls. Falls have a significant negative impact on the quality of life of elders.

Risk factors for falls can be classified as intrinsic or extrinsic. Intrinsic factors include age, muscle strength, gait and balance impairments, and neurologic or cognitive disorder. Extrinsic factors include medications, environmental hazards, and type of activity (based on hazard). The greatest risk factors for falls are previous history of falls, muscle weakness, imbalance, reduced walking speed, use of walking aids, vertigo, sedentariness, and number of medications used (polypharmacy). It is important to note that a number of these factors, such as weakness, gait and balance impairments, use of walking aids, and medications are modifiable factors. Often, patients report near falls, defined as a "loss of balance that would have resulted in a fall if sufficient recovery mechanisms (movement of the trunk or arms, change in stride length or velocity) were not activated." Near falls often precede falls and are more frequent than falls. Clinical assessment of falls should include information on near fall events. More information on fall assessment appears in the following section. Physical exercise (under the supervision of a physical or occupational therapist) is effective in reducing the frequency of falls and preventing future falls. In addition, home hazard assessment and

reduction (under the supervision of occupational therapists) reduces the frequency of fallers and the number of falls. Clinicians should consult physical and occupational therapists, as needed.

CLINICAL ASSESSMENT OF STANCE, GAIT, AND FALLS

Assessment should include a detailed medical history and clinical exam, which consists of two parts: clinical observation and standardized assessment. A summary of the clinical assessment procedures is provided in Table 15.3.

History

It is important to document the history of acute and chronic medical problems, history of near falls and falls, history of problems with balance and gait, and level of physical activity. Ask the patient about the most recent fall and ascertain the circumstances around the fall, including what the patient was doing, what caused the fall, where the fall occurred, environmental hazards that may have caused the fall, and the consequence of the fall.

It is also important to ask about the timeline of onset of gait impairments because the timeline may provide clues to diagnosis. For instance, if the onset of gait disorder is acute (minutes to hours), it may signal an infarction, hemorrhage, or head trauma. If the onset of gait disorder is between hours to days, it may be due to disorders such as multiple sclerosis, Guillain-Barré syndrome, or tumor. Gait disorders that begin over weeks to months may indicate presence of degenerative disorders of the basal ganglia or cerebellum, hydrocephalus, or chronic infections. If the gait disorder is present episodically, it may be due to multiple sclerosis or transient ischemic attack. Examples of conditions with gait disorders and the timeline of onset is shown in Figure 15.4.

Medications

Note the list of prescribed medications and if any medications and/or dosages have been recently modified.

Physical Examination

Physical examination should include an assessment of musculoskeletal function and footwear. Neurologic examination should include tests of cognitive function (using an assessment such as the Montreal Cognitive Assessment), muscle strength, reflexes, sensation, coordination, and presence of involuntary movements.

Balance and Gait Assessment

The examination begins with observation of a patient in a quiet stance. Clinicians should observe the patient from the front, back, and side. Determine if head is flexed, translated forward or backward, or tilted to one side. It is important to note if the shoulders are level or positioned asymmetrically. Examine if shoulders are hunched (rotated) forward. Note the position of the trunk to determine if it is kyphotic (rounded) as seen in

TABLE 15.3 Clinical Assessment

History	Falls and near falls Level of physical activity Complaints of gait and balance
Medications	Prescribed medications Change in medication or dosage
Most recent fall incident	1. What was the patient doing? (standing, walking, turning, bending, reaching for objects, transfers, climbing on step-stool or ladder, recreational activity) 2. What caused the fall? (dizziness, loss of balance, weakness, dual-task performance, slip/trip, fatigue, bumped into object) 3. Where did the fall occur? (indoor level surface, indoor uneven surface, outdoor level surface, outdoor uneven surface) 4. Did environmental hazard cause fall? (icy or wet surface, clutter, rugs/carpet, darkness, moving objects) 5. What was the result of the fall? (minor injury, major injury)
Physical examination	Cognitive function (eg, Montreal Cognitive Assessment) Musculoskeletal examination (range of motion, joint pain, swelling) Footwear (sandals, flip-flops, sneakers)
Neurologic examination	Muscle strength Reflexes Sensation Presence of involuntary movements Coordination
Balance and gait assessment	Clinical observation and standardized assessments. Please see **Table 15.4.**
Environmental assessment	Presence of safety grab bars Clutter and presence of area rugs or carpets Adequacy of lighting Height of chairs Surfaces (uneven, incline, stairs) Use of walking aids (cane, walker)

FIGURE 15.4 Timeline of onset of gait disorders. Schematic illustration of disorders gait syndrome acuity, and the timeline of onset (x-axis).

disorders of aging or lordotic (hyperextended). Examine if trunk is tilted to one side because this may be an indication of pain, diminished sensory feedback, or impaired vestibular system.

Upper Extremities

Healthy people tend to maintain their arms next to the trunk with slight internal rotation at the shoulder and extension at the elbows. Observe if the arm is maintained in a flexed and internally rotated posture (as is often the case in people with stroke) and if involuntary movements are present (such as writhing choreic movements in Huntington disease or resting hand tremor seen in Parkinson disease). Also note if the hand is maintained in a fixed posture because this may be a sign of dystonia.

Lower Extremities

Healthy people stand with the pelvis in a neutral position and lower limbs extended with the feet pointing straight ahead. Note if the hip and knee joints are maintained in flexion, as is sometimes seen in people with muscle tightness or weakness.

Assessment of Gait

Ensure that there is adequate space (length of 7-10 m) to conduct a comprehensive gait assessment. Observe the patient from the front, back, and sides. Note the position of the head and trunk during gait, presence or absence of arm swing, and instability during walking and turning.

- *Standard walk*: Ask the patient to walk at their comfortable pace. Observe position of the head and trunk, walking path, and length and symmetry of steps. Note presence of instability during gait.
- *Turns*: Ask the patient to turn and observe the number of steps taken to turn. Note presence of instability during turns.
- *Narrow doorway*: Ask the patient to walk through a narrow doorway. This test is provocative for freezing of gait. Note presence of freezing.
- *Tandem walk*: Ask the patient to walk heel to toe for 10 steps. Note whether the patient can perform the task without support and the number of steps taken away from a straight line.
- *Dual-task walk*: Ask the patient to walk at his or her comfortable speed while performing a secondary motor or cognitive task. Typical secondary motor tasks include carrying a cup of water or carrying a tray with a cup on it. Several secondary cognitive tasks have been employed and include the following:
  - Count backward: Give the patient a number and ask him or her to count backward by 3 (serial 3) or by 7 (serial 7). Note that performance on the serial 7 task is dependent on level of education and may be too difficult for several patients.
  - Verbal fluency: Ask the patient to generate words that begin with a certain letter (such as "d") or words that belong to a category (eg, animals).
  - Walking while talking: Ask the patient a question (such as "What did you have for breakfast today?")

In addition to clinical observation, several standardized assessments of mobility, balance, and fall risk are available, summarized in Table 15.4.

The assessment of gait can be focused by asking the following questions, which will assist in classifying the gait disorder.

1. Is the gait symmetrical?
   A. If asymmetrical, then assess whether there is pain.
      i. If pain is present → antalgic
      ii. If no pain is present, assess if there is bony deformity.
         a. If bony deformity present → orthopedic gait disorder
         b. If no bony deformity is seen → hemiplegic gait
   B. If gait is symmetrical, then move to next step.
2. Are steps short?
   A. If steps are short, examine posture.
      i. If posture stooped and no arm swing → parkinsonian gait

TABLE 15.4 Standardized Assessments of Mobility, Balance, and Fall Risk

Assessment	Details	Clinical Indication
Timed up and go	Time taken to get up from a seated position, walk 3 m, turn around, walk back, and take a seat	Increased fall risk in the following: 1. Community-dwelling elderly: >13.5 s 2. Parkinson disease: >11.5 s 3. Stroke: >14 s
Tinetti performance-oriented mobility assessment	Balance scale consists of nine items that assess balance in sitting, standing, transitions, and turning.	Total score is 28. Score >25 indicates low fall risk, score between 19 and 24 indicates medium fall risk, and scores <19 indicate high fall risk.
Berg Balance Scale	Measures performance on 14 functional tests of sitting and standing balance, transfers, turning, etc.	Total score is 56. Scores <45 indicative of increased fall risk.
Dynamic Gait Index	Measures ability to walk a distance of 6.1 m (20 ft) under external demands (such as head turns)	Total score is 24. Score <19 indicative of fall risk.
Walking while talking	Examines whether patients are able to walk while reciting the alphabet (simple) or every alternate alphabet (complex)	Community-dwelling elderly: >20 s for simple task; >30 s for complex task indicative of falls.
10-m walk	Patient is asked to walk a distance of 10 m at either a self-selected comfortable speed or fast speed. Time taken to cover middle 6-m distance is measured to eliminate the effect of acceleration and deceleration.	Household ambulator = speed <0.4 m/s Limited community ambulator = speed between 0.4 and 0.8 m/s Community ambulator = speed >0.8 m/s
Tandem walk	Measures ability to walk 10 steps tandem (heel to toe) walk	<2 completed steps indicative of fall risk
6-min walk test	Measures the distance walked in a period of 6 min along a 30-m long walkway	Distance <400 m indicates lack of aerobic capacity.

   ii. If posture is upright, and arm swing normal → Marche à petit pas
   B. If steps are normal, examine support base.
3. Is support base normal?
   A. If support base is narrow with crossing over → scissor gait
   B. If support base is wide, then examine step height.
      i. If step height is normal → cerebellar ataxic gait
      ii. If step height is high → sensory ataxic gait
   C. If support base is normal, examine step height.
      i. High step height → bilateral foot drop
      ii. If step height is normal, examine pelvic rotation.
4. Does the pelvis rotate?
   A. If pelvis rotation seen → waddling gait
   B. If pelvis rotation normal, examine joint coordination.
5. Is joint movement of lower limbs coordinated?
   A. Uncoordinated joint movements → apraxia
   B. If joint movements are coordinated, examine overall quality of gait.
6. Are gait impairments unusual and inconsistent from one trial to the next?
   A. If yes → psychogenic/functional gait

CLASSIFICATION OF GAIT DISORDERS

In neurologic disorders, gait is classified as disordered based on comparison with healthy subjects, for whom normative values through the course of aging are available. However, given the large variability of what is considered "normal" gait, caution must be used in order to describe gait patterns as impaired. Table 15.5 highlights gait impairments that are clinically evident in neurologic disorders. Several classifications have been proposed for gait disorders including anatomic, hierarchical (eg, low, mid, and high level), etiologic (eg, degenerative), or phenomenologic (eg, antalgic gait). Anatomic classification describes gait disorders based on brain pathology (eg, cerebellar gait). Hierarchical classification differentiates gait disorders into three categories based on the level of pathology (eg, low level, midlevel, and high level). Gait disorders due to peripheral sensory (eg, sensory ataxic) or motor disorders (eg, spinal muscular atrophy) are classified as low-level disorders. Disorders that occur as a result of pathology in the motor system, including motor cortical areas, basal ganglia, and cerebellum, are classified as midlevel disorders. Finally, gait disorders that result from the interaction of cognitive (frontal cortex) and motor systems (eg, Alzheimer disease) are classified as high-level disorders. Finally, classification of gait disorders by phenomenology takes into account etiology and clinical features. In this chapter, gait disorders are classified by hierarchy and pathophysiology, which more closely reflects clinical practice. The table also separates phenomena that may be observed throughout gait observation (continuous) from those that are unpredictable (episodic). According to this classification, continuous phenomena reflect the underlying pathology and compensatory mechanisms, whereas episodic phenomena are those that the patient cannot adapt to because of their unpredictability.

TABLE 15.5 Disorders of Gait

Disorder	Continuous Phenomena (Speed, Support Base, Arm Swing, Symmetry, Path)	Episodic Phenomena (Freezing of Gait, Gait Initiation, Falls)
High-Level Gait Disorders		
Alzheimer disease Gait disorder occurs late in the disease.	Slow gait speed Short step length Increased time in double support Increased variability, particularly when performing cognitive dual task	Increased risk for falls
Mild cognitive impairment (MCI)	Slow gait speed Short step length Increased time in double support Gait variability higher in amnestic MCI but not in nonamnestic MCI Poor limb coordination (foot tapping) compared with controls	Increased risk for falls and fear of falls
Vascular dementia Gait disorder occurs early in the disease.	Slow gait speed Short step length Wide support base Rigidity	Freezing of gait Imbalance and falls seen
Normal pressure hydrocephalus Gait disorder seen early in the disease in conjunction with cognitive impairment and urinary incontinence	Slow gait speed Short step length Wide support base and outward rotation of foot (may be compensation for poor balance) Asymmetric steps Low step height (shuffling steps)	Increased risk for falls
Dementia with Lewy bodies Gait impairments seen in conjunction with visual hallucinations	Slow gait speed Reduced arm swing Flexed trunk posture Rigidity	Increased risk for falls
Frontotemporal dementia Gait impairments seen in the presence of behavioral disturbances (impulsivity, disinhibition)	Slow gait speed Involuntary trunk movements Postural instability	Increased risk for falls
Psychogenic (functional) gait disorder Gait impairments seen in the presence of psychiatric disorders such as anxiety, depression, or personality disorder	Gait impairments not consistent from one assessment to the next, may have sudden onset, very severe impairments at onset, and spontaneous remissions. Astasia-abasia Knee buckling during stance Wide support base and short step length (waddling) Excessive retropulsion	Tremor and dystonia seen, although may not be observed when the patient is distracted
Midlevel Gait Disorders		
Hemiparesis	Slow gait speed Asymmetric stepping Swing phase—impaired lower limb moves in circumduction; hip hiking seen (Trendelenburg sign) Ankle may be maintained in plantar flexion and inversion leading to loss of heel strike at the beginning of stance. Stance phase—knee joint may hyperextend. Reduced arm swing on impaired side and reduced trunk rotation During dual-task gait, impairments worsen.	Increased risk for falls
Head trauma	Slow gait speed in the acute phase; resolves with time Increased time in double support may be seen Increased imbalance during tandem stance and gait Impairments more prominent during dual-task gait	Increased fall risk in the acute phase
Paraparesis	Slow gait speed Low cadence Low step height Circumduction may be seen. Decreased support base (scissoring gait) seen in patients with spasticity	Increased risk for falls due to weakness and imbalance
Parkinson disease Gait impairments seen in the presence of tremor, rigidity, and postural instability	Slow gait speed Very short step length Poor foot clearance during swing (which leads to shuffling gait) Increased temporal variability Postural instability and impaired balance seen (missteps during tandem gait) Stooped posture Limited or no arm swing During dual-task gait, Parkinson disease patients pay greater attention to secondary cognitive task as opposed to gait leading to greater gait impairments (posture second strategy).	Freezing of gait Difficulty initiating gait Increased fear of falls and increased risk for falls as disease progresses

TABLE 15.5 Disorders of Gait *(continued)*

Disorder	Continuous Phenomena (Speed, Support Base, Arm Swing, Symmetry, Path)	Episodic Phenomena (Freezing of Gait, Gait Initiation, Falls)
Midlevel Gait Disorders		
Multiple system atrophy Gait impairments seen in the presence of autonomic dysfunction and urinary incontinence	May present like Parkinson disease (slow speed, short step length) May present like cerebellar ataxia (gait ataxia—increased support base, path deviation, postural instability, impaired balance—missteps during tandem gait)	Increased risk for falls as disease progresses
Progressive supranuclear palsy	Postural instability Wide support base Rigid support base and low vertical displacement of the pelvis during gait Slow gait speed Difficulty turning (turn en bloc)	High risk for falls, increased fear of falls
Huntington disease	Slow gait speed Decreased step length Reduced cadence Increased time in double support Asymmetric step length Inconsistent step time Gait impairments worsen during secondary dual task. Chorea of limbs or trunk may increase instability. Dystonic posturing of ankle, trunk, neck or arm during gait	Increased fear of falls and greater number of falls as disease progresses
Essential tremor	Slow gait speed Reduced cadence Increased time in double support Asymmetric step length Wide support base Increased temporal variability Prominent balance impairment (missteps during tandem gait)	Increased fear of falls and greater number of falls
Cerebellar ataxia	Inconsistent step time Asymmetric step length Short step length and low step height Wide support base Increased temporal variability Increased postural sway Greater missteps during tandem gait	High risk for falls, increased fear of falls
Low-Level Gait Disorders		
1. Peripheral sensory disorders (peripheral neuropathy, posterior *column* disorder, vestibular and visual deficit)		
Sensory ataxic gait	Wide support base Postural instability increased when standing with eyes closed Increased step height Short step length Foot slap at beginning of stance phase Patients tend to look at their feet while walking.	Increased risk for falls when not using vision
2. Peripheral *motor* disorders		
Antalgic gait	Decreased weight bearing on painful limb leading to shorter stance phase Short stride length Reduced range of motion in affected joint(s) Trendelenburg sign may be seen due to pain at the hip joint.	
Spinal muscular atrophy	Slow gait speed Decreased step length Reduced cadence Wide support base Trendelenburg sign Impairments worsen with fatigue during continuous walking.	Increased risk for falls
Duchenne muscular dystrophy	Lordotic posture and anterior pelvic tilt Waddling gait (short step length, wide support base) Knee hyperextension during stance Ankle plantar flexion during swing Gait pattern does not change with continuous walking.	Increased risk for falls

Acute Stroke: The First Hour 16

Barry M. Czeisler and Stephan A. Mayer

KEY POINTS

1. Emergency head imaging combining noncontrast computed tomography (CT) with CT angiography is rapidly becoming the standard first-line imaging protocol for all patients presenting with potential stroke within 24 hours of last known well.
2. When intracerebral hemorrhage is identified, the primary management goals are to identify and reverse anticoagulation, control systolic blood pressure to 130 to 150 mm Hg, and assess for possible neurosurgical intervention.
3. Intravenous thrombolysis should be given to all eligible patients with acute ischemic stroke presenting within 4.5 hours of onset. Many previously recognized contraindications to thrombolysis are now considered relative.
4. If CT angiography identifies a large vessel occlusion, mechanical thrombectomy is the treatment of choice. For patients presenting within 6 to 24 hours, CT perfusion demonstrating a significant penumbra is key to identify eligibility for mechanical thrombectomy.

INTRODUCTION

Sudden focal neurologic deficits can result from a variety of causes, the most frequent and concerning of which is acute stroke. The two most common forms of stroke, both of which cause sudden onset of focal neurologic deficits without antecedent symptoms, are acute ischemic stroke (AIS) and intracerebral hemorrhage (ICH). Both conditions are neurologic emergencies. The symptoms of AIS and ICH (**Table 16.1**) have significant overlap necessitating imaging studies to distinguish the two conditions.

Emergency management of AIS is focused on attaining vascular reperfusion as soon as possible with the administration of intravenous tissue plasminogen activator (IV tPA) for thrombolysis, endovascular thrombectomy, or both. Time is critical, as it has been estimated that 1.9 million neurons die each minute prior to reperfusion. Every 15-minute reduction in onset-to-treatment time translates into a meaningful reduction in the risk of long-term disability at 3 months. In the case of ICH, emergency care is focused on blood pressure (BP) control, reversal of anticoagulation, and management of intracranial pressure (ICP).

This chapter focuses on the emergency management of the patient presenting with an acute focal neurologic deficit. Subsequent management after the first hour is discussed in Chapter 36 for AIS and in Chapter 39 for ICH.

TABLE 16.1 Symptoms and Signs of Acute Stroke

Facial asymmetry
Lateralized limb weakness or clumsiness
Lateralized numbness or paresthesias
Slurred or confused speech
Visual disturbances (diplopia or difficulty seeing)
Dizziness or vertigo
Gait instability
Headache
Alterations in level of consciousness

PHASE 1: INITIAL MANAGEMENT AND IMAGING

Due to the importance of early intervention in stroke, the emphasis of emergency department (ED) evaluation should not be on identifying subtle, unusual, or interesting neurologic signs but on the following five simple priorities. These tasks are ideally performed in parallel by four different personnel immediately upon patient arrival (eg, the ED attending, resident, nurse, and stroke neurologist):

1. Assess level of consciousness and ensure adequate airway, breathing, and circulation.
2. Obtain the history with precise attention to the specific time of onset (or time last known to be at neurological baseline) of symptoms along with a list of current medications.
3. Establish large-bore (preferably 18 gauge) intravenous access and obtain admission labs.
4. Perform a National Institutes of Health Stroke Scale examination.
5. Obtain head computed tomography (CT) imaging as soon as possible.

Modern emergency stroke management is evolving toward a paradigm that resembles trauma resuscitation. The initial goal is to minimize door-to-CT time because subsequent management is entirely dependent on the results of the initial imaging. For AIS, the conventional goal is to obtain CT within 20 minutes and to start tPA infusion within 45 minutes of arrival to the ED (Fig. 16.1). Currently, 75% of U.S. hospitals have a mean tPA door-to-needle time of less than 60 minutes despite nationwide efforts to streamline and expedite care.

New acute stroke care delivery models emphasizing parallel processing and lean management principles that exclude unnecessary steps have been shown to significantly reduce door-to-needle time for AIS. In the Helsinki model, physicians have proven the feasibility of safely administering IV tPA within 20 minutes of hospital arrival. In this paradigm, prehospital

FIGURE 16.1 National Institute of Neurological Disorders and Stroke timeline targets for attaining an intravenous tissue plasminogen activator door-to-needle time of 60 minutes or less. Abbreviations: ASPECTS, Alberta Stroke Program Early CT Score; CT, computed tomography; ED, emergency department; MD, doctor of medicine; NIHSS, National Institutes of Health Stroke Scale; tPA, tissue plasminogen activator.

notification by ambulance triggers the stroke code, which then leads to the following:

1. Notification of the stroke team and ED staff, which assembles to meet the patient at the CT scanner
2. Transmitting the mobile phone number of any first responders or eyewitnesses to the stroke team to facilitate obtaining the history
3. Establishing a medical record number and hospital chart prior to arrival
4. Preordering the CT scan
5. Notification of pharmacy so that tPA or an anticoagulation reversing agent can be provided as soon as possible after the CT scan

Given the complexity of coordinated personnel, resources, preparation, and teamwork that is required, most municipalities triage acute stroke patients directly to hospitals that are designated as primary stroke centers. After the initial resuscitation is completed, if the patient is unusually complex or critically ill, consideration should be given to transferring the patient to the nearest comprehensive stroke center.

Initial Survey and Vital Signs Prior to Computed Tomography

Level of Consciousness

Intracerebral hemorrhage with mass effect as well as ischemic strokes of the brainstem, thalami, or large cortical regions can cause impairment in mental status. Depressed level of consciousness may in turn lead to aspiration of oropharyngeal contents or ineffective respirations due to upper airway obstruction, either of which may necessitate endotracheal intubation prior to further evaluation and management.

Blood Pressure

Hypertension occurs commonly as a nonspecific response to cerebral injury and can be present in both AIS and ICH. Elevated BP is a strong indicator that the patient is actually having a stroke as opposed to a stroke mimic. Early BP elevation may be advantageous in AIS, allowing for increased cerebral perfusion to the *ischemic penumbra*, areas of marginally perfused brain. Aggressive BP reduction within the first few hours of AIS onset can lead to worsening of the neurologic deficit and therefore should be avoided.

The BP should only be lowered prior to noncontrast CT if the systolic BP is higher than 220 mm Hg, diastolic BP is higher than 120 mm Hg LEVEL 2,[1] or it is suspected that hypertension is leading to acute end-organ damage (eg, acute myocardial infarction, aortic dissection, or cardiogenic pulmonary edema). If BP is lowered, a systolic BP of 180 mm Hg is a reasonable target. The preferred agents and their dosages for emergency BP control in acute stroke are shown in **Table 39.3**. Blood pressure goals are reevaluated after CT imaging has established the etiology of the symptoms and, for AIS, once decisions are made regarding reperfusion therapy.

Heart Rate

Atrial fibrillation (AF) with rapid ventricular response, the most common significant arrhythmia in patients with acute stroke, or other tachyarrhythmias can occur on presentation and may necessitate stabilization prior to obtaining CT. Diltiazem 10 mg IV or metoprolol 5 mg IV are commonly used initial therapies for AF with rapid ventricular response in this setting. A cardiac monitor should be placed if there is any concern about heart rate or if the patient reports chest pain or palpitations. Routine electrocardiography should be obtained in acute stroke patients but is only required prior to CT if there is significant dysrhythmia or if an acute coronary syndrome is suspected.

Respirations and Breathing

Obvious respiratory distress should trigger placement of an oxygen saturation monitor and oxygen via nasal cannula, targeting an oxygen saturation greater than or equal to 94%. A decision then needs to be made about whether to proceed directly to CT or to defer until adequate airway and ventilation can be assured. Patients with severe dyspnea or significantly impaired level of consciousness (stupor or coma) should be intubated prior to CT scan because failure to control the airway can lead to respiratory arrest or severe aspiration.

Temperature

In general, it is not necessary to measure body temperature prior to CT in a patient with acute stroke unless meningitis is suspected.

Initial History

If eyewitnesses are available, obtain a collateral history from them to corroborate the patient's account. Whenever possible, confirm the patient's history with emergency medical system personnel, and ask prehospital providers to provide mobile phone numbers of eyewitnesses who might not be immediately present in the ED. Be sure to inquire about the following points.

1. ***Exactly when did the stroke symptoms first begin?***
   If the onset of symptoms cannot be reported by the patient and were not witnessed, ask when the patient was last known well. For those who present on waking from sleep, the physician must determine whether the symptoms were present immediately upon awakening or shortly thereafter after a brief period of normalcy. If they truly awoke with the symptoms, the last known well time may be the time when they went to sleep the prior evening but often will be a time that they awoke transiently in the middle of the night.
2. ***What were the initial symptoms?***
   A maximal deficit at onset in a fully alert patient supports cerebral infarction and suggests embolism in particular. Ask specifically if the patient's deficits have worsened or fluctuated since onset. Early headache, vomiting, or change in level of consciousness supports ICH. Inquire specifically about lateralized weakness, numbness, or other classic symptoms of acute stroke (see **Table 16.1**).
3. ***Was any seizure activity observed?***
   Postictal deficits from seizures can mimic stroke. Seizures manifesting as focal motor convulsions or generalized tonic-clonic activity can also occur at the onset of ICH or AIS, but this is unusual.
4. ***What is the patient's medical history and neurologic baseline?***
   Assess for stroke risk factors such as hypertension, diabetes mellitus, dyslipidemia, cigarette smoking, AF, carotid stenosis, and prior transient ischemic attacks or strokes. A patient presenting with worsening of an existing or previously resolved neurologic deficit may have recrudescence of their prior deficits due to systemic derangements such as fever, hypoglycemia, or hypoxia (**Table 16.2**).
5. ***What medications is the patient taking?***
   Ask particularly about anticoagulants or antiplatelet agents. Use of these agents not only predisposes to ICH but can also limit therapeutic options in the setting of ischemic stroke.

Establish Intravenous Access and Draw Admission Labs

Ideally, two peripheral IVs should be placed, at least one of which should be 18 gauge to facilitate advanced imaging studies (ie, CT angiography or CTA) if necessary. Routine admission labs should be drawn including complete blood count, serum chemistries, prothrombin time/partial thromboplastin time/international normalized ratio (INR), troponin I, and other tests as indicated (eg, liver function tests, toxicology screen). Point-of-care finger stick blood glucose level should also be obtained.

National Institutes of Health Stroke Scale Examination

The National Institutes of Health Stroke Scale (**Table 16.3**) is a simple algorithm for quantifying the severity of neurologic deficits in patients with acute stroke. Eleven items are tested, and a score is generated on a scale ranging from 0 (no deficit) to 42 (comatose and quadriplegic). In expert hands, the test takes only several minutes to administer. Scores higher than 20 in patients with AIS imply a high risk of large territory infarction and a very poor prognosis if reperfusion is not attained. Once the history and examination are completed, the lesion should be able to be localized clinically.

Perform Head Computed Tomography Imaging

Noncontrast head CT (NCHCT) is by far the most readily available test for differentiation of AIS and ICH and the only one that must absolutely be obtained prior to administering thrombolytic therapy for AIS. The ability to obtain timely CT scans is greatly improved by having the CT scanner located within the ED. To minimize any delays in treatment, the patient should ideally be taken directly from the ambulance to the CT scanner with coordinated evaluation and intervention performed just outside the CT suite or on the CT table.

Studies show that obtaining CT imaging is the rate-limiting step in acute stroke management, so optimization of door-to-CT times should be of high priority. *The main differential diagnosis in acute stroke is infarction versus hemorrhage*. All further management decisions will depend on making this distinction.

More recently, CTA has proved to be indispensable for diagnosing large vessel occlusions (LVO), which respond best to endovascular mechanical thrombectomy. To minimize delays in the diagnosis and treatment of LVO, many stroke systems are combining NCHCT with CTA as the initial imaging protocol for all stroke codes. CT perfusion is also often performed to assess tissue viability and potential candidacy for thrombectomy when an LVO is identified 6 to 24 hours from last known well.

Analysis for Hemorrhage

Blood is hyperdense (bright) and easily identifiable on NCHCT (**Fig. 16.2A**). Intracerebral hemorrhage appears as a discrete focus of blood that displaces the surrounding brain parenchyma. Intracerebral hemorrhage volume, a strong predictor of 30-day mortality and functional outcome, can be quickly measured using the ABC / 2 method (see **Fig. 39.3**). Two diameters (A + B), measured at right angles on the slice that corresponds to the epicenter of the hemorrhage, are measured in centimeters. The third diameter perpendicular to that plane (C) is measured by multiplying the number of slices on which the bleed is apparent by each slice thickness (usually 5 mm, expressed 0.5 cm).

TABLE 16.2 Differential Diagnosis of Acute Neurologic Deficits

Diagnosis	Clinical Characteristics
Stroke	
Ischemic stroke	• Deficits that are maximal at onset suggest embolism. • Sometimes preceded by transient ischemic attacks • Headache is uncommon. • BP often elevated
Intraparenchymal hemorrhage	• Often presents with headache and/or nausea and vomiting • Deficit commonly worsens over minutes to hours as hemorrhage expands. • Loss of consciousness at onset is rare. • BP often extremely elevated
Subarachnoid hemorrhage	• Typically presents with sudden "thunderclap headache" • Often associated with transient loss of consciousness • Focal symptoms are unusual.
Stroke Mimics	
Seizure with postictal deficit	• Occurs in aftermath of focal motor activity or an unwitnessed seizure • Deficits gradually improve and resolve over minutes to hours after onset. • Can be differentiated from ischemic stroke with DWI MRI • EEG may show corresponding epileptiform activity.
Migraine with aura	• Typical patient has a history of migraine and prior similar events. • Can present with weakness, aphasia, neglect, visual changes, and/or sensory loss • Symptoms may precede, be concurrent with, or follow a typical migraine headache. • Typically occurs in younger patients with no stroke risk factors
Recrudescence of a prior focal deficit	• Sudden worsening of old stroke symptoms (does not cause new symptoms) • Triggered by fever, hypoxia, hypoglycemia, hyponatremia, or other metabolic disturbances • Focal deficits are typically accompanied by features of encephalopathy.
Stroke Mimics *(continued)*	
Subdural hematoma	• May not have a clear history of recent trauma in elderly patients with acute-on-chronic bleeding • Typically presents with focal deficits or subacute confusion and gait disturbance in an elderly patient • Headache is common but not universal.
Brain tumor or abscess	• Usually has a subacute to chronic presentation but can suddenly worsen due to associated seizure or bleeding into the tumor • Often with symptoms of headache, especially when recumbent
Multiple sclerosis or other demyelinating disease	• Usually has a more subacute presentation but can mimic acute stroke at times • Often has history of prior deficits in varying locations • Can be differentiated from ischemic stroke with DWI MRI • Affects younger patients with no stroke risk factors
Peripheral (labyrinthine) vertigo	• Can mimic an infarct in the brainstem or cerebellum causing acute vertigo • Can be differentiated from ischemic stroke with careful examination (horizontal head impulse test, characterization of nystagmus, and cover-uncover test[a]) in most but not all cases • Definitive exclusion of ischemic stroke requires DWI MRI, although DWI can also miss small brainstem infarcts.
Hypertensive encephalopathy (posterior reversible encephalopathy syndrome)	• Most commonly presents with altered mental status, headache, vision changes, or seizures • Usually does not cause unilateral symptoms • BP usually elevated • Can occur in younger patients with no stroke risk factors
Conversion disorder	• A diagnosis of exclusion • Detailed neurologic exam sometimes reveals inconsistencies suggesting a nonphysiologic cause of symptoms. • Positive signs of misdirected effort may be elicited (eg, Hoover sign).

Abbreviations: BP, blood pressure; DWI, diffusion-weighted imaging; EEG, electroencephalogram; MRI, magnetic resonance imaging.
[a]See Chapter 5 for details of the Head Impulse Nystagmus Test of Skew (HINTS) examination for differentiating central from peripheral vertigo.

The product of these three diameters is divided by two as a simplification of the equation for the volume of an ellipsoid. Patients with ICH volumes of less than 30 mL have potential for a good prognosis and have a small risk of early deterioration, whereas those with ICH volumes between 30 and 70 mL are at higher risk for early deterioration due to mass effect. Patients with hemorrhages greater than 70 mL were traditionally considered to be uniformly lethal, although survival with reasonable recovery can be attained in this group with emergency surgery, such as hemorrhage evacuation or hemicraniectomy.

Whenever ICH is present, be sure to check for the following radiographic findings:

- *Subarachnoid hemorrhage* (Fig. 16.2B) in association with ICH suggests a ruptured aneurysm and requires angiography.
- *Intraventricular hemorrhage* (Fig. 16.2C) in association with ventricular enlargement requires neurosurgical evaluation for possible emergent ventriculostomy.
- *Fluid/fluid levels* within a hematoma (Fig. 16.2D) result from separation of red blood cells and plasma and are indicative of a coagulopathy.
- *Edema, mass effect, and midline shift* usually lead to delayed neurologic deterioration when associated with a large hemorrhage (>30 mL). Perihematomal edema takes several hours to develop after ICH and is therefore not usually seen on initial head CT. An abnormally large or an irregular amount of edema associated with hemorrhage on initial presentation may suggest hemorrhagic conversion of infarcted tissue, bleeding associated with neoplasm, or venous infarction from dural sinus thrombosis.

Analysis for Ischemic Stroke

Infarction does not cause consistent changes on CT within 6 hours of stroke onset. Infarction is suspected when a patient presenting with sudden onset of neurologic deficits has a normal CT scan. Over a period of approximately 6 hours, regions of

TABLE 16.3 The National Institutes of Health Stroke Scale[a]

1a. Level of consciousness (LOC):
0 = Alert; keenly responsive
1 = Not alert but arousable by minor stimulation to obey, answer, or respond
2 = Not alert; requires repeated stimulation to attend or is obtunded and requires strong or painful stimulation to make movements (not stereotyped)
3 = Responds only with reflex motor or autonomic effects or totally unresponsive, flaccid, and areflexic
1b. LOC questions: The patient is asked the month and his or her age.
0 = Answers both questions correctly
1 = Answers one question correctly
2 = Answers neither question correctly
1c. LOC commands: The patient is asked to open and close the eyes and then to grip and release the nonparetic hand.
0 = Performs both tasks correctly
1 = Performs one task correctly
2 = Performs neither task correctly
2. Best gaze: horizontal eye movements
0 = Normal
1 = Partial gaze palsy; gaze is abnormal in one or both eyes.
2 = Forced deviation or total gaze paresis not overcome by the oculocephalic maneuver
3. Visual loss:
0 = No visual loss
1 = Partial hemianopia
2 = Complete hemianopia
3 = Bilateral hemianopia (blind including cortical blindness)
4. Facial palsy:
0 = Normal symmetric movements
1 = Minor paralysis (flattened nasolabial fold, asymmetry on smiling)
2 = Partial paralysis (total or near-total paralysis of lower face)
3 = Complete paralysis of one or both sides (absence of facial movement in the upper and lower face)
5. Motor arm: The limb is elevated for 10 s, scored separately for left and right.
0 = No drift; limb holds 90° (or 45°) for full 10 s.
1 = Drift; limb holds 90° (or 45°) but drifts down before full 10 s; does not hit bed or other support
2 = Some effort against gravity; limb cannot get to or maintain (if cued) 90° (or 45°), drifts down to bed, but has some effort against gravity.
3 = No effort against gravity; limb falls.
4 = No movement
6. Motor leg: The limb is elevated for 5 s, scored separately for left and right.
0 = No drift; leg holds 30° position for full 5 s.
1 = Drift; leg falls by the end of the 5-s period but does not hit bed.
2 = Some effort against gravity; leg falls to bed by 5 s but has some effort against gravity.
3 = No effort against gravity; leg falls to bed immediately.
4 = No movement
7. Limb ataxia:
0 = Absent
1 = Present in one limb
2 = Present in two limbs
8. Sensory:
0 = Normal; no sensory loss
1 = Mild to moderate sensory loss; patient feels pinprick is less sharp or is dull on the affected side; or there is a loss of superficial pain with pinprick, but patient is aware of being touched.
2 = Severe to total sensory loss; patient is not aware of being touched in the face, arm, and leg.
9. Best language:
0 = No aphasia; normal
1 = Mild to moderate aphasia
2 = Severe aphasia; all communication is through fragmentary expression.
3 = Mute, global aphasia; no usable speech or auditory comprehension
10. Dysarthria:
0 = Normal
1 = Mild to moderate dysarthria; patient slurs at least some words and, at worst, can be understood with some difficulty.
2 = Severe dysarthria; patient's speech is so slurred as to be unintelligible in the absence of or out of proportion to aphasia.
11. Extinction and inattention:
0 = No abnormality
1 = Visual, tactile, auditory, spatial, or personal inattention or extinction to bilateral simultaneous stimulation in one of the sensory modalities
2 = Profound hemi-inattention or extinction to more than one modality; does not recognize own hand or orients to only one side of space

[a]Total score ranges from 0 (normal) to 42 (comatose and quadriplegic). For informational purpose only. Accurate and reliable scoring of the National Institutes of Health Stroke Scale requires strict adherence to a standardized testing protocol. Refer to https://www.ninds.nih.gov/sites/default/files/nih_stroke_scale_508c.pdf for complete instructions on how to conduct and score the test and for smartphone applications than can assist in performance and scoring.

FIGURE 16.2 Computed tomography scans of brain hemorrhage. **A:** Intracerebral hemorrhage. **B:** Subarachnoid hemorrhage. **C:** Intraventricular hemorrhage. **D:** Acute intracerebral hemorrhage with fluid/fluid level indicative of a coagulopathy.

ischemia will gradually develop into an area of hypodensity as the tissue infarcts. The presence of a large hypodensity on NCHCT in an AIS patient should prompt reevaluation and careful scrutiny of the reported time of onset.

The Alberta Stroke Programme Early CT Score (ASPECTS) was developed to quantify the extent of infarction on initial CT imaging for middle cerebral artery (MCA) infarction (Fig. 16.3). Loss of differentiation between gray and white matter in the cortex and deep structures such as the caudate, putamen, or globus pallidus results from early ischemic injury and portends eventual progression to irreversible infarction (Fig. 16.4). The score is composed of seven cortical regions and three subcortical regions of the MCA territory totaling 10 points for a normal study from which 1 point is subtracted for each area of visualized infarct. This score has high interrater reliability and serves to quantify infarction, predict outcome, and stratify patients regarding the potential benefit of reperfusion therapies.

Acute thrombus in a proximal vessel such as the MCA ("dense MCA sign") or basilar artery can create a hyperdense appearance to the vessel on NCHCT. The presence of a hyperdense vessel may have clinical use in the acute setting because it helps to confirm the diagnosis of LVO and may lead clinicians to mobilize neurointerventional teams for endovascular mechanical thrombectomy.

PHASE 2: POSTCOMPUTED TOMOGRAPHY EMERGENCY MANAGEMENT

Intracerebral Hemorrhage

The following management guidelines apply specifically to spontaneous ICH. Refer to Chapter 40 for management of *subarachnoid hemorrhage* and Chapter 47 for management of *traumatic brain injury*.

Diagnose and Reverse Coagulopathy and Platelet Dysfunction

The presence of blood on CT mandates that a prothrombin time /INR, partial thromboplastin time, and platelet count are sent as

FIGURE 16.3 Anatomic regions evaluated in the Alberta Stroke Programme Early CT Score. A score of 10 indicates no evidence of early ischemic change from which 1 point is subtracted for each region of infarction. Patients with scores below 7 are at high risk for hemorrhagic transformation if given intravenous tissue plasminogen activator. Abbreviations: C, caudate; I, insula; IC, internal capsule; L, lentiform nucleus; M, middle cerebral artery territories 1 through 6.

FIGURE 16.4 Early cerebral infarction with loss of gray-white definition and sulcal effacement. (*Arrows* indicate anterior and posterior borders of the involved territory of the middle cerebral artery.)

STAT tests to confirm normal values as soon as possible. Next, confirm whether or not the patient is taking any anticoagulants that do not significantly affect these values (eg, dabigatran, rivaroxaban, apixaban, low molecular weight heparins). Also, inquire about antiplatelet agents (eg, aspirin, clopidogrel, ticagrelor, dipyridamole, prasugrel). A basic metabolic panel is also useful to show evidence of uremia, which can cause a qualitative platelet defect.

Suggested protocols for the reversal of different forms of anticoagulation or platelet dysfunction are shown in **Table 16.4**. *If there is a clear history of current use, steps to reverse anticoagulation or restore platelet function should be considered urgently to minimize the risk of hemorrhagic expansion* LEVEL 1.[2] In patients with vitamin K antagonist–associated ICH, successful reversal of the INR to less than 1.5 combined with control of systolic BP is associated with a reduced risk of hematoma enlargement.

Reversal of platelet dysfunction in patients with acute ICH is controversial and data are limited. Desmopressin is often used with meager evidence to support its use. One recent trial reported that platelet transfusions are not helpful, and possibly harmful, in ICH patients on antiplatelet agents LEVEL 1.[3] Platelet transfusion certainly remains reasonable in ICH patients with thrombocytopenia (<50,000/μL).

Control Severe Hypertension

In contrast to the AIS patient, continued hypertension may harm the ICH patient by causing expansion of the hemorrhage and worsened perihematomal edema. Two randomized trials of BP goals in the setting of ICH have yielded somewhat contradictory results. Lowering systolic BP to less than 150 mm Hg appears to

TABLE 16.4 Strategies for Reversal of Anticoagulation or Platelet Dysfunction in Acute Intracerebral Hemorrhage

Agent	Treatment Strategy	Comments
Warfarin (vitamin K antagonist that results in reduced synthesis of factors II, VII, IX, and X)	Administer vitamin K 10 mg IV over 30 min *and* Four-factor PCC 25-50 U/kg IV *or* FFP 2-4 200 mL units IV	If available, PCC is preferable, as it results in a substantially quicker time to INR reversal than FFP using a much smaller volume of infusion. The goal should be to lower the INR to <1.5.
Dabigatran (direct thrombin inhibitor)	Give activated charcoal if the medication was ingested within the past 2 h *and* Administer idarucizumab 5 g IV *or* Consider emergent hemodialysis	Idarucizumab specifically normalizes coagulation parameters in patients on dabigatran but has not yet been studied in a trial to prove benefit in clinical outcomes. There is limited data to support other therapies, but four-factor PCC or factor VIIa can be considered.
Rivaroxaban, apixaban, edoxaban, fondaparinux (Xa inhibitors)	Consider andexanet alfa in either low dose (400 mg IV then 4 mg/min IV infusion) or high dose (800 mg IV then 8 mg/min IV infusion) for 120 min *or* Consider a four-factor PCC 25-50 U/kg IV	Andexanet alfa specifically normalizes coagulation parameters associated with Xa inhibitors but has not yet been studied in a trial to prove benefit in clinical outcomes. It is approved for reversal of rivaroxaban and apixaban. <8 h since last dose: • Apixaban up to 5 mg: low-dose andexanet • Apixaban >5 mg: high-dose andexanet • Rivaroxaban up to 10 mg: low-dose andexanet • Rivaroxaban >10 mg: high-dose andexanet >8 h since last dose: low-dose andexanet There is limited data for the benefit of PCC for reversal of Xa inhibitors.
UFH	For IV bolus UFH given <1 h ago, administer 1 mg of protamine sulfate for every 100 units of UFH. If UFH was given 1-2 h ago, give 1 mg of protamine sulfate for every 200 units of UFH. If UFH was given >2 h ago, give 1 mg of protamine sulfate for every 400 units of UFH.	For patients receiving an IV infusion of UFH, administer protamine sulfate 1 mg for every 100 units given in the past 2 h.
Enoxaparin, dalteparin (LMWH)	If LMWH was given <8 h ago, give 1 mg of protamine sulfate per 100 anti-Xa units of LMWH. If LMWH was given 8-24 h ago, give 1 mg of protamine sulfate per 200 anti-Xa units of LMWH. If bleeding continues, an additional dose of 0.5 mg per 100 anti-Xa units can be administered.	Enoxaparin has 100 anti-Xa U/mg, whereas dalteparin has 156 anti-Xa U/mg.
Antiplatelet agents, platelet abnormalities (ie, uremia), or thrombocytopenia	*Give* DDAVP 0.3 μg/kg IV over 30 min. *Consider* 1 unit of single-donor platelets (or 6 units of pooled platelets) in ICH patients with uremia, thrombocytopenia, or in those undergoing neurosurgical intervention. *Avoid* platelet transfusion in nonoperative ICH.[a]	Limited data is available to support these interventions. For thrombocytopenia, transfuse platelets to goal of >50,000/μL.

Abbreviations: DDAVP, desmopressin acetate; FFP, fresh frozen plasma; ICH, intracerebral hemorrhage; INR, international normalized ratio; IV, intravenous/intravenously; LMWH, low molecular weight heparin; PCC, prothrombin complex concentrate; UFH, unfractionated heparin.

[a]Trial data suggests no benefit of platelet transfusion to reverse the effects of anti-platelet agents in patients with ICH, and platelet transfusion in this setting may be associated with harm LEVEL 1.[3] It might be reasonable to consider platelet transfusion in patients with planned neurosurgical intervention to minimize intraoperative bleeding.

be potentially beneficial, but lowering systolic BP further to less than 120 mm Hg may be associated with worsened renal injury without any additional benefit LEVEL 1.[4,5] Therefore, a goal of 130 to 150 mm Hg may be most appropriate. Nicardipine or clevidipine infusion is preferable because of their reliable dose-response characteristics and quick onset and offset times. If these short-acting agents are unavailable, labetalol can be administered initially as IV pushes followed by an infusion (see Table 39.3). Nitrates such as sodium nitroprusside should be avoided due to their potential to cause cerebral vasodilation and elevated ICP.

Treat Elevated Intracranial Pressure or Symptomatic Mass Effect

If the NCHCT shows significant mass effect (midline shift, effacement of the basal cisterns, or both) and the patient has depressed level of consciousness, empiric treatment of ICP should be initiated. Hyperventilation causes vasoconstriction that will lower cerebral blood volume and thus lower ICP. It should be used transiently as a bridge to further intervention in intubated patients who show signs of transtentorial herniation (ie, dilated pupil). In general, a PCO_2 level of 30 is targeted. If the patient is intubated and agitated or coughing, sedation should be considered. Bolus osmotherapy with mannitol 1 to 1.5 g/kg IV can be easily administered through a peripheral IV. Alternatively, 30 mL of 23.4% hypertonic saline can be given, but this requires central venous access. Steroids should not be administered because they have been shown to be ineffective for management of cerebral edema after ICH LEVEL 1[6] and may increase the risk of infectious complications (see also Chapter 34).

Consider External Ventricular Drain Placement or Placement of an Intracranial Pressure Monitor

Obstructive hydrocephalus typically develops in ICH patients who also have a significant amount of intraventricular hemorrhage.

Any new enlargement of the temporal horns of the lateral ventricles on NCHCT in a patient with altered level of consciousness should prompt consideration of external ventricular drain placement for management of hydrocephalus and control of ICP. Without diversion of cerebrospinal fluid, patients with acute hydrocephalus can deteriorate rapidly. If significant mass effect is present in a patient who is ineligible for surgical evacuation, a parenchymal ICP monitor may be considered to allow for optimization of ICP management (see Chapter 34).

Consider Emergent Surgical Hematoma Evacuation

For cerebellar hemorrhage with associated clinical deterioration, brainstem compression, or hydrocephalus, suboccipital surgical decompression with or without hematoma evacuation is recommended LEVEL 1.[2] For supratentorial hemorrhage, however, there is far less consensus. The Surgical Trial in Intracerebral Hemorrhage was unable to show definitive benefit for craniotomy with evacuation of supratentorial ICH within 72 hours of onset compared with best medical therapy LEVEL 1.[7,8] Most likely, the incision in cerebral cortex required to surgically evacuate deeper hemorrhage leads to further neurologic injury that negates any benefit. Despite these results, there is some suggestion that patients with active deterioration due to mass effect may still benefit from surgical evacuation, as these patients were not randomized into the trials. New minimally invasive strategies for hemorrhage evacuation have been developed, such as endoscopic aspiration, although the benefit of these techniques has not yet been proven in clinical trials. Hemicraniectomy is also used at times as a salvage procedure but is similarly of unproven benefit in this setting. Nevertheless, all of these surgical options should be considered on a case-by-case basis, especially in cases where the clinical assessment is that the patient is unlikely to survive without surgery and could otherwise possibly achieve a good clinical outcome.

Consider Anticonvulsant Therapy

Hemorrhage can cause cortical irritation and the development of seizure activity. If clinical seizures occur or electrographic seizures are noted on electroencephalogram, patients should be given an IV antiepileptic medication such as levetiracetam 60 mg/kg (loading dose for active seizures) followed by a maintenance dose of 1 g every 12 hours. Prophylactic treatment with anticonvulsants has not been shown to be beneficial and, in some cases, may be associated with harm, and thus routine use of prophylactic anticonvulsants should be avoided LEVEL 1.[2]

Consider Advanced Imaging

Intracerebral hemorrhage is most commonly due to hypertension when it occurs in the putamen, globus pallidus, caudate, thalamus, pons, or cerebellum. Cortical ICH occurs more frequently in the elderly and usually results from *amyloid angiopathy*, the deposition of amyloid into the arterial wall. However, ICH may also be caused by aneurysms (if adjacent to the subarachnoid space), arteriovenous malformations, dural arteriovenous fistulas, cavernous malformations, tumors, hemorrhagic conversion of infarcted tissue, or other less common etiologies. Young patients, those with atypical CT findings, and those without a history of hypertension or anticoagulant use should undergo further imaging studies to evaluate for an underlying lesion. Imaging options include CTA, magnetic resonance imaging (MRI)/magnetic resonance angiography, or catheter angiography. CT angiography can be performed on the CT table immediately after NCHCT identifies ICH, provided the patient remains stable and does not urgently require any additional treatments.

Disposition

Due to high risks of neurologic deterioration and development of medical complications, most patients with acute ICH should be admitted to an intensive care unit for further evaluation and management.

Acute Ischemic Stroke

For patients presenting with an acute neurologic deficit who show no signs of hemorrhage on noncontrast CT, the presumptive diagnosis is ischemic stroke and the primary goal is to provide eligible patients with reperfusion therapy as soon as possible.

In the setting of acute cerebrovascular occlusion, there will usually be an area of the brain with very poor blood flow where the neurons die quickly, which is often called the *ischemic core*. Surrounding this area, however, is the *ischemic penumbra*, which can be small or large depending on collateral blood flow patterns in individual patients. This region has cells that are usually electrically quiescent because they shut down their electrical signaling to conserve energy in the face of impaired oxygen and glucose delivery due to vascular occlusion. The neurons in this region, unlike in the ischemic core, are still alive at presentation but will gradually die as time passes. As such, the goal of all reperfusion therapies is timely reperfusion to the ischemic penumbra, to prevent cell death in this area, and thereby ultimately improve the patient's neurologic function and outcome.

Thrombolysis with IV tPA and endovascular treatments both lose efficacy as acute ischemia progresses to infarction. Optimization of each step of acute stroke management is required to ensure timely therapies. In the world's best stroke centers, thrombolysis with IV tPA can be administered within 20 minutes after ED arrival, and endovascular thrombectomy can be initiated within 60 minutes.

Indications for Intravenous Tissue Plasminogen Activator

With the completion of the National Institute of Neurological Disorders and Stroke trial in 1995, administration of IV tPA (specifically alteplase) became the standard of care for acute reperfusion therapy in AIS within 3 hours of symptom onset LEVEL 1.[9] Thrombolysis with alteplase increases the chances of a good recovery at 3 months after infarction from approximately 26% to 39% corresponding to a number needed to treat of 8 with no effect on mortality. Unfortunately, alteplase also carries a 6% risk of symptomatic hemorrhagic conversion, most commonly in patients given alteplase at later time points relative to symptom onset or in those with extensive signs of early ischemic change as evidenced by an ASPECTS lower than 7. Despite this increase in hemorrhage, however, there was no difference in mortality and ultimate outcomes were improved in the alteplase group.

In 2008, the European Cooperative Acute Stroke Study III trial confirmed the safety and efficacy of IV alteplase up to 4.5 hours after symptom onset in a subgroup of patients who were younger than 80 years of age. The benefit of alteplase in this subset is less than those treated within 3 hours. Patients given alteplase within the 3.0- to 4.5-hour window also have increased rates of hemorrhagic conversion and worsened mortality compared with patients given tPA within 3 hours of onset LEVEL 1.[10]

Speed of attaining reperfusion is by far the most important determinant of the efficacy of tPA. The number needed to treat

to achieve one functionally independent patient after ischemic stroke increases from as little as 5 for patients treated within 90 minutes of onset to 15 when alteplase is given within the 3.0- to 4.5-hour window. For unselected patients who present beyond 4.5 hours from onset, IV alteplase is not of proven benefit and may cause harm because the risk of hemorrhagic conversion increases LEVEL 1.[11] It has recently been shown that patients with an unknown time of onset who undergo urgent MRI showing diffusion-weighted imaging (DWI) hyperintensity but no fluid-attenuated inversion recovery hyperintensity (suggesting recent onset) can benefit from IV tPA administration LEVEL 1,[12] but urgent MRI is not currently available at most centers, which limits its utility. CT perfusion imaging is more widely available, and patients 4.5 to 9 hours after stroke onset with a large penumbra demonstrated on CT perfusion imaging may still benefit from IV tPA LEVEL 1[13] but the benefit of thrombolysis in this setting is more modest, and further evidence is needed to support its widespread use.

Contraindications to Tissue Plasminogen Activator Administration

The 1995 National Institute of Neurological Disorders and Stroke trial used strict exclusion criteria derived from expert opinion at the time, which were subsequently translated into contraindications for tPA administration. However, these rigorous contraindications may not necessarily define the full population of patients who might benefit from tPA. Table 16.5 shows the relative strength of various contraindications to tPA therapy. These updated recommendations largely reflect case series, cohort studies, and 25 years of clinical experience since the original approval of alteplase. It is crucial to use sound clinical judgment when giving tPA in the setting of a relative contraindication and to fully explain how this may alter the risks of therapy relative to the expected benefit. The most commonly encountered exclusions are discussed in the following sections.

TABLE 16.5 Strength of Evidence for Contraindications to Tissue Plasminogen Activator Therapy[a]

Clinical Scenario	Strength of Contraindication
CT evidence of hemorrhage	Absolute
Completed infarct signs involving >1/3 of the MCA territory	Absolute
Time of symptom onset unknown	Absolute
History of coagulopathy or anticoagulant use or documented elevation of INR (>1.7) or aPTT (>1.5 × control)	Relative, strong
Thrombocytopenia (platelet count <100,000 μL)	Relative, strong
SBP >185 mm Hg or DBP >110 mm Hg[b]	Relative, moderate
Major surgery or serious trauma within preceding 14 d	Relative, moderate
Glucose <50 or >400 mg/dL[b]	Relative, moderate
Pregnancy	Relative, moderate
Stroke or serious head trauma within preceding 3 mo	Relative, weak
Seizure at onset of stroke	Relative, weak
Rapidly improving or minor symptoms (eg, pure sensory, minimal weakness)	Relative, weak
Gastrointestinal, urinary tract, or other significant bleeding within preceding 21 d	Relative, weak
Significant MI within past 4 wk or symptoms of post-MI pericarditis	Relative, weak
Arterial puncture at a noncompressible site within preceding 7 d	Relative, weak
Lumbar puncture within preceding 7 d	Relative, weak

Abbreviations: aPTT, activated partial thromboplastin time; CT, computed tomography; DBP, diastolic blood pressure; INR, international normalized ratio; MCA, middle cerebral artery; MI, myocardial infarction; SBP, systolic blood pressure.

[a]This information is intended to serve only as a guideline. Successful and safe use of intravenous tissue plasminogen activator (tPA) has been reported despite the presence of one or more of these complications. Decisions regarding the risks and benefits of tPA should be individualized.

[b]Blood pressure and glucose can be urgently corrected and then tPA can be administered.

Early Infarct Signs

Early ischemic changes on imaging are clearly associated with higher rates of hemorrhagic conversion. Early ischemic changes should not exclude patients from thrombolysis if the extent of these changes is small (ASPECTS of 7-9).

Improving or Mild Symptoms

Although as many as 30% of AIS patients are not administered tPA due to rapidly improving or minor stroke syndromes, 25% of these patients still have poor functional outcomes or death after stroke. The AIS patients with minor or resolving deficits may still benefit from thrombolysis and should be considered on a case-by-case basis.

Blood Pressure Higher Than or Equal to 185/110 mm Hg

Severe hypertension is thought to increase the risk of hemorrhagic transformation after thrombolysis, although good evidence of cause and effect is scant. It is reasonable to rapidly control BP to lower than 185/110 mm Hg and start tPA while continued efforts are made to maintain target BP with a continuous infusion agent such as nicardipine or clevidipine (see Table 39.3).

Seizure at Onset

Seizures at onset are unusual in AIS and raise the strong possibility that the patient may have a postictal rather than ischemic deficit. Nevertheless, tPA is safe in patients with seizures at onset, and it is reasonable to give tPA if the index of suspicion for AIS is high.

Warfarin With International Normalized Ratio Greater Than 1.7

A history of liver failure or warfarin use in patients with AIS mandates a STAT INR. Otherwise, there is no need to check coagulation routinely prior to giving tPA, as the prevalence of unexpected coagulopathy is very low in this population. There is conflicting evidence as to whether tPA is associated with an increased risk of hemorrhagic transformation when the INR is either below or mildly above 1.7 among patients taking warfarin.

Abnormal Blood Glucose

Elevated blood glucose has been associated with a decreased likelihood of neurologic improvement, decreased rates of recanalization, and a higher risk of hemorrhagic conversion after thrombolysis for AIS. Treatment of hyperglycemia has not yet

been shown to modify outcome, but it nevertheless is prudent to control blood glucose within a tight normal range when administering tPA. Both hyper- and hypoglycemia raises the possibility of a stroke mimic due to "unmasking" of a prior focal deficit.

Old Age

Although those older than age 80 years do not benefit as much from thrombolysis, patients given tPA still show improved outcomes compared with those in whom tPA is withheld. Thrombolysis with IV tPA should not be withheld from elderly patients without other contraindications.

Tissue Plasminogen Activator and Stroke Mimics

The prevalence of potential AIS that proves to be a stroke mimic is as high as 20% to 25% in some regions, most of which represent seizure, complicated migraine, or conversion disorder. MRI, which can more definitively differentiate stroke from mimics, leads to delays that reduce the efficacy of tPA in improving neurologic outcomes. Fortunately, several studies show that tPA administration to stroke mimics is not associated with ICH or other complications. A rate of treating stroke mimics with thrombolysis of up to 15% is considered acceptable in most active stroke centers.

Dosage of Intravenous Tissue Plasminogen Activator

Alteplase is supplied in powder form and must be reconstituted with sterile water prior to administration. For eligible patients, 0.9 mg/kg of IV alteplase is administered up to a maximum dose of 90 mg with the initial 10% given as an IV push and the remainder infused over 1 hour.

Post–Tissue Plasminogen Activator Blood Pressure Management

The BP should be strictly maintained at lower than 180/105 mm Hg for at least 24 hours after tPA is administered to minimize the risk of hemorrhagic conversion. Because the half-life of tPA is extremely short, a radial arterial line can be safely placed for BP monitoring 1 hour after discontinuation of the infusion because direct pressure can be effectively applied if bleeding occurs at this location. Intravenous short-acting drip antihypertensive agents that can be easily titrated are optimal to definitively achieve this goal and to avoid large swings in BP.

Aspirin

Patients who do not receive IV tPA should be given aspirin 81 to 325 mg as soon as possible. For those who receive IV tPA, aspirin administration should be delayed for 24 hours after tPA infusion to prevent hemorrhagic conversion and then started thereafter. Early aspirin administration after AIS has been shown to decrease the risk of early recurrent stroke, death, and dependency at 1 year, although the number needed to treat is approximately 100 LEVEL 1.[14,15]

Role of Endovascular Therapy

An important limitation of IV tPA is that it fails to recanalize the occluded vessel in 40% of cases. When larger clots occlude the major large intracranial vessels—the proximal MCA, internal carotid artery terminus, or basilar artery—recanalization rates are even worse and outcomes remain poor despite IV tPA administration. If an LVO is present, endovascular intervention to extract the clot from the vessel using a suction or retrievable stent device can then be attempted (see Chapter 25 for details). In 2015, several trials, including Multicenter Randomized Clinical Trial of Endovascular Treatment for Acute Ischemic Stroke in the Netherlands LEVEL 1,[16] Endovascular Treatment for Small Core and Anterior Circulation Proximal Occlusion with Emphasis on Minimizing CT to Recanalization Times LEVEL 1,[17] and three additional trials (see **Table 35.5**), showed that endovascular intervention can dramatically improve functional outcome, whether or not patients received adjunctive IV tPA. Such benefit has been shown in trials to occur with endovascular intervention performed up 6 hours or more from stroke onset.

FIGURE 16.5 Computed tomography angiogram maximum intensity projection image (coronal view) demonstrating total occlusion of the left M1 segment of the middle cerebral artery.

In order to effectively select patients for endovascular therapy, acute vessel imaging is required, usually done with CTA (**Fig. 16.5**). Many stroke centers have established protocols in which tPA therapy is initiated in the CT scanner immediately after the noncontrast CT is obtained. This allows the team to proceed directly with a CT angiogram without delaying tPA administration. Even more recently, some hospitals and health care systems have adopted a "CTA-for-All" policy, in which all patients triggering a stroke code within 24 hours of last known well automatically get an NCHCT and CTA as the initial imaging study, regardless of the baseline National Institutes of Health Stroke Scale score. The rationale for this is to expedite the diagnosis of LVO in all potentially treatable patients, including those with wake-up strokes or late presentation. In these protocols, routine documentation of a normal serum creatinine level is waived owing to the urgency of the situation and the low risk of serious contrast-induced nephropathy (<1%). Demonstration of LVO then triggers an interventional "secondary page" that mobilizes the interventional team with the goal of beating a 60-minute "picture-to-puncture" time interval.

For patients presenting beyond 6 hours from onset, more advanced imaging can help determine potential eligibility for

endovascular therapies. Using CT perfusion with software calculating the volume of core infarction and penumbra to assess eligible patients, the Endovascular Therapy Following Imaging Evaluation for Ischemic Stroke trial showed a significant benefit with thrombectomy performed out to 16 hours after last known well in those with a core infarct volume less than 70 mL, a ratio of penumbral tissue to core infarct volume of 1.8 or more, and an absolute volume of penumbra of 15 mL or more LEVEL 2.[18] Similarly, using DWI-MRI or CT perfusion (CTP) to measure core infarction and clinical assessment to indirectly measure the ratio of penumbra to core infarction, the DWI or CTP Assessment with Clinical Mismatch in the Triage of Wake-Up and Late Presenting Strokes Undergoing Neurointervention with Trevo trial showed benefit of mechanical thrombectomy in selected patients as far out as 24 hours after onset LEVEL 2.[19] Thus, these therapies have the potential to improve patient outcomes far beyond the traditional 4.5-hour time window for IV tPA.

Patients may sometimes be agitated and always require some form of anesthesia during the thrombectomy procedure, which can be as brief as 20 minutes or take over 2 hours. The two main anesthetic techniques, intubation with general (deep) anesthesia or conscious sedation (also known as *monitored anesthesia care*), yield similar long-term results. Perhaps the most important aspect of periprocedural care is to avoid excessive drops in BP.

Even if mechanical thrombectomy is not being pursued, vessel and perfusion imaging may clarify or confirm sites of cervical vessel occlusion, guide BP management, affect disposition, and establish prognosis. Therefore, CTA can be useful in many cases.

Disposition

Ischemic stroke patients should be transferred to a stroke unit or a neuro-ICU whenever possible depending on the clinical scenario, including active comorbidities and the immediate risk of neurologic deterioration.

Acute Spinal Cord Syndromes 17

Natalie Weathered and Noam Y. Harel

KEY POINTS

1. The majority of cases of acute nontraumatic spinal cord syndromes (transverse myelitis) are caused by inflammation. Up to 30% of cases remain idiopathic despite extensive testing.
2. Features of the history, including time course and risk factors, are key to refining the etiology.
3. Spinal cord magnetic resonance imaging with and without contrast and lumbar puncture are critical tests that may inform diagnosis and guide treatment.
4. Be wary of neurogenic spinal shock, which may lead to systemic hypotension and worsened cord perfusion.

INTRODUCTION

Patients presenting with acute spinal cord syndromes represent true neurologic emergencies. Pathologic damage to the cord is usually incomplete. Therefore, time is cord: There is opportunity to salvage (and peril of losing) vital cord tissue and function over the ensuing minutes and hours after presentation. Minimizing secondary damage can make the difference between a patient retaining independent daily function or requiring 24-hour care. This chapter deals largely with nontraumatic myelopathy. See Chapter 48 for more on traumatic spinal cord injury (SCI).

Transverse myelitis is the term applied to most forms of acute nontraumatic myelopathy. However, this term is a description rather than a diagnosis. A broad range of underlying etiologies may be responsible. The clinician must first localize and then differentiate the type of damage in order to initiate the most effective interventions. Thorough workup reduces the percentage of transverse myelitis cases that remains idiopathic to roughly 30%.

EPIDEMIOLOGY

Approximately 17,000 new cases of acute traumatic SCI occur in the United States annually, with around 300,000 individuals living with SCI in the United States. Motor vehicle accidents and falls are the leading causes. The epidemiology of nontraumatic acute SCI is harder to measure. Extrapolated estimates from Canada and Australia suggest an incidence of approximately 22,000 and prevalence of about 400,000 individuals with nontraumatic SCI in the United States.

PATHOBIOLOGY

Spinal Cord Anatomy

To aid with localization, recall that the caudal spinal cord segments do not align with the vertebrae bearing the same names. Be wary of patients with "T12" or "L2" spine injuries—patients with traumatic or compressive myelopathy are often labeled by *vertebral* level of injury rather than cord *segmental* level of injury. The spinal cord ends around L1, with the roots of the cauda equina below that vertebral level (Fig. 17.1). An L2 vertebral injury will therefore result in damage to the cauda equina, not the cord per se.

Motor System

Most corticospinal projections decussate in the caudal medulla to form the lateral corticospinal tract (CST) (Fig. 17.2) Roughly 5% of corticospinal projections run ipsilaterally in the anterior CST. Other descending tracts involved in motor function, generally of more axial and proximal limb muscles, include the rubrospinal tract (just ventral to the lateral CST) and the tecto-, vestibulo-, and reticulospinal tracts (just lateral to the anterior CST). Because they are more diffusely branched, fibers of these non-CST motor tracts tend to show higher degrees of sparing after SCI and can mediate significant restoration of function.

Sensory System

Fibers of the spinothalamic tract travel rostrally within Lissauer's tract for one to two spinal segments before synapsing within the dorsal horn and crossing to the contralateral anterolateral system. Therefore, a focal process causing unilateral disruption of this pathway will result in loss of pain and temperature sensation on the opposite side beginning one to two segments below the lesion. Most fibers mediating proprioception, vibratory sensation, and two-point discrimination travel within the ipsilateral dorsal columns to the gracilis and cuneatus nuclei of the lower medulla, although some proprioceptive signals ascend via the dorsal and ventral spinocerebellar tracts.

Autonomic System

Parasympathetic preganglionic neurons are found within four brainstem nuclei (cranial nerves III, VII, IX, and X) of which only the vagus nerve contributes to autonomic control below the head. Parasympathetic preganglionic neurons also reside in cord segments S2-4. Notably, even subtle lesions affecting the spinal cord above the S2 level can disrupt bladder inhibitory circuits, resulting in urinary urgency and frequency. Sympathetic preganglionic neurons are located within the intermediolateral nucleus of the thoracic and upper lumbar cord. Sympathetic circuits arising from the upper thoracic levels (T1-5) increase heart rate and

FIGURE 17.1 Relation of spinal nerve roots to vertebrae.

FIGURE 17.2 Anatomy of the spinal cord (cross-section). Tract lamination: C, cervical segments; L, lumbar segments; S, sacral segments; T, thoracic segments. (From Brazis PW, Masdeu JC, Biller J. *Localization in Clinical Neurology*. 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2007.)

contractility, whereas sympathetic circuits from T5-12 increase vasoconstriction in the splanchnic bed and lower extremities. In individuals with cord lesions at or above the T6 level, unregulated splanchnic vasoconstriction can increase systemic blood pressure to dangerous, even lethal levels, in the phenomenon of autonomic dysreflexia.

Vascular Anatomy

The anterior spinal artery and two posterior spinal arteries run longitudinally along the spinal cord. Branches of the single anterior spinal artery are responsible for two-thirds of the cord's cross-sectional area, whereas branches of the two posterior arteries serve a combined one-third of the cord's area. Therefore, the anterior portion of the cord is more susceptible to ischemia (Fig. 17.3).

The spinal arteries are fed by segmental radicular arteries, which are notoriously variable between individuals. The artery of Adamkiewicz is one of the largest radicular arteries, most commonly arising from the 9th to 12th intercostal arteries on the left. This artery is vulnerable to occlusion by aortic aneurysms and aortic repair procedures, resulting in a high rate of catastrophic cord ischemia and paraplegia. Rostral to the artery of Adamkiewicz, there is a relative paucity of collateral blood flow, making the midthoracic region particularly susceptible to ischemia from systemic hypotension.

Syndromic Pathology

Inflammation

Inflammatory myelopathy is the most common form of acute transverse myelitis. A wide range of etiologies may be responsible, ranging from neurologic manifestations of systemic autoimmune disease to primarily neuroautoimmune attack to parainfectious cross-reactions. Antibody-, complement-, and/or cell-mediated immune attack may occur against cell surface or intracellular antigens within neurons or glial cells. Autoantigens may be innocent bystanders that happen to mimic microbial antigens, leading to cross-reaction with an immune system honed to fight infection. Autopsy series have revealed monocytic, lymphocytic, and microglial infiltration into parenchyma and perivascular spaces. In most cases, damage is more prominent in white matter, with demyelination and axonal injury predominating over gray matter or neuronal inflammation.

FIGURE 17.3 The vascular supply of the spinal cord. (From Brazis PW, Masdeu JC, Biller J. *Localization in Clinical Neurology*. 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2007.)

Ischemia

As mentioned earlier, the anterior two-thirds of the cord, especially at thoracic levels, is highly susceptible to ischemia. The *anterior spinal artery syndrome* comprises acute bilateral weakness and pain/temperature sensory loss, usually associated with loss of bowel and bladder control. Hypotension may occur through a spinal shock-like syndrome, which further exacerbates ongoing cord ischemia.

Infection

Although only a small percentage of systemic viral infections invade the cord parenchyma, the results may be permanent damage and paralysis. Enteroviruses such as polio and enterovirus D68 and flaviviruses such as West Nile virus directly target anterior horn cells (lower motor neurons), leading to acute flaccid paralysis with little to no chronic motor recovery. Herpesviruses more often affect dorsal horn (sensory neurons) and white matter, resulting in recurring lifelong flares of neuralgic pain. Bacterial infections of the spine usually cause epidural abscesses that result in myelopathy via compression (see below).

Compression

In contrast to inflammatory pathology, compression often damages segmental gray matter more than white matter. This is especially true in the cervical cord, where compression often presents as a "central cord syndrome": The upper extremities show flaccid weakness and sensory loss to pain and temperature, whereas the legs show milder spastic paresis, with bladder urgency. Acute traumatic compression is covered in Chapter 48. Acute nontraumatic compression usually occurs through epidural neoplasm, abscess, or hematoma. Almost all epidural neoplasms are metastatic to the vertebral bodies rather than the epidural space per se. Therefore, symptoms usually present with progressively severe pain (arising from periosteal irritation), followed by compression of anterior aspects of the cord, with prominent weakness and pain/temperature loss. Breast, lung, prostate, kidney, and colon cancers are the most common primary sources. Abscesses originate either through local trauma/disruption or hematogenously in patients with systemic infection. Key demographics include illicit parenteral drug users with endocarditis and patients with mechanical heart valves after dental procedures. Spinal epidural hematomas most often occur via trauma (including iatrogenic trauma), especially in patients on anticoagulants or with underlying coagulopathy. In contrast to epidural metastases, abscesses and hematomas usually compress the cord posteriorly.

DIAGNOSIS

A patient bought to the emergency department with bilateral leg paralysis after a motor vehicle accident does not require extensive deliberation over the differential diagnosis (see Chapter 48). However, acute cord syndromes can occur under many different circumstances, ranging from mechanical to vascular, infectious, inflammatory, neoplastic, and toxic etiologies (Table 17.1). A careful history regarding remote or recent trauma, other systemic symptoms, or toxic habits may help narrow your differential.

TABLE 17.1 Differential Diagnosis for Acute Spinal Syndromes

Compressive/Mechanical	**Infectious**
Trauma	Viral gray matter/acute flaccid paralysis
Disk herniation/subluxation	Poliovirus
Epidural abscess	Enterovirus
Epidural hematoma	Coxsackieviruses A and B
Epidural neoplasm/metastasis	West Nile virus
Vertebral compression fracture	Japanese encephalitis
Vascular	Tick-borne encephalitis
Stroke	Viral white matter/ longitudinal myelitis
Dural arteriovenous fistula	Herpes simplex virus
Arteriovenous malformation	Varicella-zoster virus
Cavernous malformation	Cytomegalovirus
Inflammatory	Epstein-Barr virus
Multiple sclerosis	Influenza
Neuromyelitis optica	Bacterial
Transverse myelitis	*Mycoplasma pneumoniae*
Acute disseminated encephalomyelitis	Syphilis
Sarcoidosis	Tuberculosis
Paraneoplastic	Lyme
Systemic lupus erythematosus	Fungal
Antiphospholipid antibody syndrome	*Cryptococcus neoformans*
Sjögren syndrome	*Coccidioides immitis*
Mixed connective tissue disease	*Blastomyces dermatitidis*
Behçet disease	*Histoplasma capsulatum*
Toxic/Metabolic	*Candida* species
Heroin	*Aspergillus* species
Konzo	Zygomycetes
Arachnoiditis after angiographic/myelographic contrast agents	Parasitic
Methotrexate toxicity	*Schistosoma* species
Cytarabine toxicity	*Toxoplasma gondii*
Amphotericin B toxicity	*Taenia solium* (cysticercosis)
Neoplasm	

Determining the rate of symptom progression proves critical, as patients whose symptoms reach maximal involvement within minutes are more likely to have a mechanical or vascular cause rather than an infectious, inflammatory, or neoplastic cause.

Focused History

Patients with acute spinal cord dysfunction are at risk for catastrophic cardiac and respiratory complications. Therefore, before taking the history, one must quickly assess airway, breathing, and circulation (ABCs). Once these ABCs (and cervical spine) are stabilized, key questions can determine etiology and localization before any physical or radiologic examination.

Etiology

- What is the *time course*? Although spinal cord ischemia does not usually present as suddenly as cerebral ischemia, patients reach a functional nadir within 4 to 12 hours, whereas patients with inflammatory or infectious myelopathies usually take 4 to 21 days to reach a nadir.
- Was there a gradual change in *gait* (stiffness, fatiguability) or bladder (urgency, nocturia) function in the weeks or months prior to presentation? That would point to a slowly encroaching mass (neoplastic or mechanodegenerative).
- Is there a history of *trauma*? Be wary of vertebral compression fracture after otherwise innocuous falls in patients with osteoporosis or occult vertebral metastasis.
- Was there any recent *surgery* that may have led to global hypotension or local cord ischemia? Aortic aneurysm procedures are notorious for causing the latter.
- Is there any known history of *cancer* or recent unexplained weight loss? Vertebral or epidural metastasis may be the presenting symptom of cancer in up to 20% of patients.
- Is the patient *immunocompromised* or are any recent *infectious symptoms* such as fevers, chills, or cough present? Back pain and fever in an intravenous drug abuser should raise red flags for possible epidural abscess. In 30% to 60% of idiopathic transverse myelitis cases, an antecedent respiratory, gastrointestinal, or systemic illness exists.
- Any *visual* symptoms? Concurrent acute nontraumatic myelopathy and optic neuritis suggest neuromyelitis optica (NMO).
- Is there a history of *coagulopathy*, *nutritional deficiency*, *environmental exposures*, or anything else that could guide the investigation?

Localization

- What is the distribution of any *weakness*? Thoracic and lumbar cord syndromes cause weakness in the lower extremities (paraparesis), whereas cervical syndromes affect all four limbs (tetraparesis).
- What is the distribution of any *numbness or paresthesias*? As with weakness, sensory findings are usually bilateral, although when a lesion is mostly on one side of the cord, there may be relative sparing of vibration and proprioception contralaterally and sparing of pain and temperature sensation ipsilateral to the lesion (Brown-Séquard syndrome). Description of a band or belt-like sensation around the trunk raises strong suspicion for a thoracic cord syndrome.
- Is there any *pain* present? Is it local to the back (worrisome for epidural metastasis or abscess), or does it follow a segmental distribution that might help localize the lesion?
- Is there any evidence of *bowel or bladder dysfunction*? Quite often, subtle changes in bladder function such as increased frequency and urgency (especially at night, when it is termed *nocturia*) may occur days, weeks, or even months prior to what otherwise presents as an acute cord syndrome. Conversely, lesions affecting the lumbosacral cord may present with bladder hypotonia, leading to retention, overflow incontinence, and frequent urinary tract infection.

Focused Exam

General Exam

Cardiovascular

Lesions at or above T6 place the patient at risk of unbalanced sympathetic-parasympathetic drive. Therefore, these patients may present with neurogenic shock: hypotension, bradycardia, or other cardiac arrhythmias including asystole. These patients are also at risk for autonomic dysreflexia: episodes of extreme hypertension (due to excessive sympathetic vasoconstriction of the splanchnic vessel bed) associated with symptoms such as diaphoresis, piloerection, facial flushing, and headache (all due to parasympathetic-mediated vasodilation above the lesion). These episodes most often have an identifiable trigger such as bladder or bowel irritation.

Pulmonary

Any lesion between the C3-5 levels may affect phrenic motoneurons. Thoracic lesions may affect accessory muscles of inspiration. The astute examiner must observe for excess work of breathing and auscultate for diminished breath sounds.

Temperature

Fever in the context of acute myelopathy may point to epidural abscess. Look for risk factors for immunocompromise and signs of parenteral drug abuse such as "track marks"; inspect sites of recent surgery.

Genitourinary and Gastrointestinal

Acutely, bladder and bowel tone may be decreased, leading to urinary retention and severe constipation. Therefore, the rectal exam and checking the postvoid residual are required.

Neurologic Exam

See **Table 17.2** for a summary of typical findings associated with specific syndromes.

Strength and Reflexes

CST damage results in upper motor neuron weakness: Below the lesion, one observes spasticity and hyperreflexia (often but not always including an extensor response to noxious plantar stimulation). Ventral horn involvement results in lower motor neuron weakness *at* the lesion levels with decreased or flaccid tone and hyporeflexia. Atrophy takes weeks or longer to develop. Note that cervical injuries often demonstrate *both* types of weakness—lower motor neuron weakness *at* the cervical level and upper motor neuron weakness *below* the lesion (due to damage of the passing CSTs). Additionally, a period of *spinal shock* lasting up to several days may result in the patient presenting with flaccid tone and diffuse hyporeflexia regardless of upper or lower motor neuron involvement. This is more common in traumatic SCI (see Chapter 48). Key muscle groups useful for localizing spinal levels include elbow flexors (C5), wrist extensors (C6), elbow extensors (C7), intrinsic hand muscles (C8-T1), hip flexors (L2), knee extensors (L3), ankle dorsiflexors (L4), and ankle plantarflexors (S1).

Sensory

A sensory "level," with sharply demarcated sensory loss below the level of the lesion, may be seen, especially in thoracic lesions. Depending on the distribution of the lesion in the anteroposterior and mediolateral axes, different combinations of bilateral, ipsilateral, and contralateral sensory loss may be observed, such as loss of vibration and proprioception (dorsal columns) and/or loss of pain and temperature (anterolateral system). Useful dermatomal landmarks include the nipple line (T4) and navel line (T10).

Imaging

Urgent magnetic resonance imaging (MRI) with T2-weighted imaging is required for the workup of acute myelopathy unless the patient has an absolute contraindication to MRI. In cases where MRI is not feasible, the best option for imaging compressive lesions of the cord is computed tomography myelography, which involves injecting contrast dye into the subarachnoid space. Gadolinium contrast MRI sequences should always be performed unless the patient's renal function is compromised because enhancement represents a critical element in the diagnostic workup. In patients presenting with leg weakness, hypertonia, and hyperreflexia, the clinician should avoid the common mistake of imaging the lumbosacral cord. This upper motor neuron presentation strongly argues for a thoracic, not a lumbosacral lesion. Regardless, total spinal cord survey may be warranted in many situations, such as to assess for multiple lesions or diffuse meningeal involvement. Unfortunately, MRI alone does not usually provide a definitive diagnosis. Diffusion-weighted imaging, which is highly sensitive for cerebral ischemia, has relatively poor resolution and sensitivity for cord ischemia.

Laboratory Evaluation

A lumbar puncture should almost always be performed for the workup of acute myelopathy. Cerebrospinal fluid (CSF) and serum tests to consider are listed in **Table 17.3**. In addition to the basic CSF laboratory tests of glucose, protein, and cell count, oligoclonal band assessment and an immunoglobulin G index

TABLE 17.2 Classic Spinal Cord Syndromes

Syndrome	Typical Causes	Clinical Characteristics
Central cord syndrome (syringomyelia)	Underlying cervical spondylosis with hyperextension injury; damage relatively greater to gray than white matter	Weakness in upper extremities > lower extremities; may have neurogenic bladder dysfunction and varying degrees of sensory loss at or below the lesion (often in a "cape-like" distribution)
Brown-Séquard syndrome	Penetrating trauma (many nonpenetrating injuries show partial asymmetric syndromes)	Ipsilateral motor and vibration/proprioception loss below the lesion, contralateral pain/temperature loss two levels below the lesion
Anterior cord syndrome	Hypotensive event leading to infarct within the midthoracic region, or hyperflexion injury leading to compression of the anterior spinal artery	Bilateral loss of motor, pain/temperature sensation below the lesion with preservation of vibration/proprioception/two-point discrimination
Posterior cord syndrome	Vitamin B_{12} deficiency, multiple sclerosis, vascular malformations, atlantoaxial subluxation	Bilateral loss of vibration/proprioception/two-point discrimination with preservation of motor, pain/temperature sensation below the lesion
Cauda equina syndrome	Disk herniation, tumor	Asymmetric lower extremity weakness, patchy impaired sensation to all modalities, loss of deep tendon reflexes as well as bulbocavernosus reflex and anal wink, often with low back and radicular pain
Conus medullaris syndrome	Disk herniation, trauma, tumor	Symmetrical sacral > lumbar weakness (may have normal leg strength), saddle anesthesia, bowel/bladder dysfunction

TABLE 17.3 Laboratory Evaluation for Acute Spinal Cord Syndromes

Source	Laboratory Test
Lumbar puncture	Cell count with differential Glucose Total protein Gram stain and culture HSV 1 and 2 PCR VZV PCR VZV IgG/IgM EBV PCR Enterovirus PCR VDRL Oligoclonal band profile (needs matching serum sample) IgG index Angiotensin-converting enzyme (ACE)
Serum	Aquaporin-4 antibody ACE ANA dsDNA antibodies Anti-Smith antibodies Anti-Ro/SSA antibodies Anti-La/SSB antibodies Anti-RNP antibodies Anti-slc-70 antibodies RPR Paraneoplastic

Abbreviations: ANA, antinuclear antibodies; EBV, Epstein-Barr virus; HSV, herpes simplex virus; IgG, immunoglobulin G; IgM, immunoglobulin M; PCR, polymerase chain reaction; RPR, rapid plasma regain; VDRL, Venereal Disease Research Laboratory; VZV, varicella-zoster virus.

are usually indicated—this requires parallel CSF and serum collection to infer the relative synthesis rate of new antibodies within the CSF compartment.

Of the basic CSF lab tests, pleocytosis is common in infection, NMO, acute disseminated encephalomyelitis (ADEM), and sarcoidosis. In NMO, neutrophils and eosinophils predominate, whereas in ADEM and sarcoid, the profile is usually lymphocytic. Supernumerary oligoclonal bands are present in 85% of multiple sclerosis CSF samples and only rarely in ADEM and NMO.

MANAGEMENT

Initial Stabilization

Spinal Stabilization

As part of the "ABCs" of emergency medicine, any acute traumatic spinal cord presentation should be immediately stabilized with a rigid cervical collar in the emergency department if not already applied in the field. Please see Chapter 48 for more on the management of acute spinal trauma.

Intensive Care Unit Admission

Intensive care, within a neurologic intensive care unit if available, is preferred in any patient who has cardiovascular or pulmonary symptoms or who has rapid progression of neurologic symptoms.

Pulmonary Management

Patients with cervical lesions should be monitored for respiratory compromise even if intubation is not immediately needed. Hypercarbia often precedes hypoxia, so abnormalities are often present on arterial blood gas before they become evident on pulse oximetry.

Cardiovascular Management

Spinal shock may result in decreased sympathetic outflow, leading to neurogenic hypotension, bradycardia, and arrhythmia. Therefore, patients should be closely followed using telemetry and frequent or continuous blood pressure monitoring. Fluid resuscitation and vasopressors should be used as needed to keep mean arterial pressure at least 85 mm Hg or spinal cord perfusion pressure at least 60-65 mm Hg (level 3 evidence) to prevent exacerbation of cord dysfunction from systemic hypoperfusion. This is especially critical in the setting of suspected cord ischemia.

Etiology-Specific Treatment

Inflammation

In the acute setting, parenteral glucocorticoids always play a major role in treating inflammatory myelopathy. Regimens range from dexamethasone at doses ranging 4 to 10 mg every 4 hours to methylprednisolone 1,000 mg/d. When patients do not respond to glucocorticoids, or when presentation of inflammatory myelitis is especially severe, other immunomodulating interventions such as plasma exchange, intravenous immunoglobulin, cyclophosphamide, or rituximab are frequently initiated. There are no level 1 guidelines or standards of care.

Ischemia

As mentioned earlier, blood pressure support (mean arterial pressure >85 mm Hg) is critical for maintaining cord perfusion. In some cases, placement of a lumbar drain to lower CSF pressure and improve spinal cord perfusion pressure can be considered. If vascular imaging studies can localize a thrombus, malformation, or dissection causing the ischemia, then catheter-based intervention may be possible. A role for intravenous or intra-arterial tissue plasminogen activator has been proposed, but no controlled studies have been performed.

Infection

For bacterial abscesses, empiric antibiotics should be administered urgently, followed by percutaneous drainage or surgical resection, and a specific antibiotic regimen once cultures and sensitivity are determined. For viral parenchymal infections, options are unfortunately sparse. Aside from acyclovir and valacyclovir for varicella zoster myelitis, treatment for most viral infections consists of supportive care. Multiple modes of immunomodulatory treatment, such as intravenous immunoglobulin, plasma exchange, interferons, and others, have been used to theoretically counter parainfectious inflammation, but no clear benefit has been demonstrated.

Compression

As noted earlier, time is cord. Once a compressive etiology is confirmed, whether the cause is neoplastic, structural, infectious, or hematoma, definitive treatment involves direct decompression via resection or drainage. Not surprisingly, the prognosis for ambulation depends on preintervention ambulatory status and time between symptom onset and intervention.

OUTCOME

It is critical to recall that most spinal syndromes are anatomically incomplete. Even when patients demonstrate complete loss of motor and sensory function below a lesion during the acute period, there is almost always a degree of spared tissue traversing the lesion. Assuming further damage is halted, there is a realistic chance at regaining function. Based on data from traumatic SCI, patients with complete sensorimotor loss during the acute period have a greater than 3% chance at regaining antigravity strength in paralyzed muscles at 1 year. Likewise, those with complete motor but incomplete sensory deficits acutely have a nearly 25% chance at regaining antigravity strength.

Patients with ischemic myelopathy likely have similar odds of recovery as trauma patients—most who present with severe sensorimotor paralysis remain paralyzed, but functional recovery is by no means miraculous. Unfortunately, even though early radiation and surgical decompression can maintain or restore ambulatory status in patients with metastatic compressive myelopathy, their average life span after presentation is only 6 months.

For patients with acute transverse myelitis without abnormalities on brain MRI, recurrence may occur in ~25% to 30% of cases. If brain abnormalities are present at the time of initial presentation, between 60% and 90% of patients will eventually progress to a formal diagnosis of multiple sclerosis. For patients with nonrecurrent inflammatory myelitis, roughly a third make full recoveries, a third have moderate long-term disability, and a third have severe long-term disability.

Focal Mass Lesions 18

Michelle Bell, Alexander G. Khandji, and Fabio M. Iwamoto

KEY POINTS

1. Elevated intracranial pressure is a neurologic emergency, and immediate measures (ie, bed elevation and bolus osmotherapy) should taken to reduce the intracranial pressure.
2. Brain focal masses are typically caused by cancers (primary or metastatic), infections (abscess or cerebritis), or other inflammatory processes.
3. Magnetic resonance imaging of the brain with and without contrast is always recommended in evaluation of focal mass lesions unless there is a medical contraindication (eg, pacemaker).
4. If imaging demonstrates significant swelling and impending herniation, patient should receive steroids followed by open biopsy and decompression.
5. In patients with AIDS, toxoplasmosis and primary central nervous system lymphoma are the most common etiologies.

INTRODUCTION

The differential diagnosis of an undifferentiated focal brain mass lesion is broad and the clinical presentation quite variable. This chapter discusses the major etiologic categories of focal brain mass lesions—namely, tumors, abscesses, and other inflammatory lesions—and present an algorithm for implementing empiric management in stable patients while a definitive diagnosis is pursued.

EMERGENT MANAGEMENT OF SYMPTOMATIC INTRACRANIAL MASS EFFECT

The first step in management of a focal mass lesion is to assess for increased intracranial pressure (ICP) and signs of herniation in patients with radiographic signs of mass effect and midline shift.

Common symptoms and signs of increased ICP include headache, vomiting, depressed level of consciousness, papilledema, abducens nerve palsies, and systolic hypertension with or without bradycardia (Cushing reflex). As mass effect worsens, in addition to the expected contralateral hemiparesis, patients develop motor signs *ipsilateral* to the lesion as a result of lateral and rotation displacement of both corticospinal tracts. Common signs include stiffening, hyperreflexia, and extensor plantar responses. With further brain tissue displacement, transtentorial herniation leads to ipsilateral third nerve palsy ("blown pupil").

If the clinical assessment is concerning for elevated ICP, it is imperative to take immediate measures to reduce it. First-line interventions include head elevation to 30 degrees LEVEL 4[1] and bolus osmotherapy with either 20% mannitol 1 g/kg intravenous (IV) or 30 mL of 23.4% hypertonic saline if there is central venous access LEVEL 4.[2,3] If level of consciousness is depressed with inability to maintain and protect the airway, the patient should be intubated and hyperventilated to $PaCO_2$ of 30 mm Hg while awaiting definitive treatment (see Chapter 111 for further details) LEVEL 4.[4]

If there is no evidence of increased ICP, further management should be determined by the clinician's assessment of the most likely underlying cause of the mass lesion. This chapter discusses the diagnostic evaluation of undifferentiated mass lesions and the initial steps in management depending on the suspected diagnosis.

CAUSES OF FOCAL BRAIN LESIONS

Figure 18.1 shows common causes of focal lesions of the brain not consistent with stroke or trauma based on location.

Brain Tumors

Tumors account for the majority of focal brain mass lesions. In adults, *metastatic tumors* account for approximately 50% of symptomatic brain tumors (**Fig. 18.2**). The most common primary tumor to metastasize to the brain is lung cancer. Approximately 50% to 60% of brain metastasis originate from lung cancer, with 25% to 40% being of non–small cell lung cancer origin and 5% to 15% being of small cell lung cancer origin. About 20% of lung cancer brain metastases are found at the time of initial diagnosis. The next most common sources of brain metastases are breast cancers (15%-30%), melanoma (10%), renal cancer (5%), and gastrointestinal cancers (5%) (see Chapter 101).

Approximately 70,000 primary brain tumors are diagnosed each year. The most common form of primary brain tumor found in adults are *meningiomas* (35%). These dural-based masses enhance densely with gadolinium on magnetic resonance imaging (MRI) (**Fig. 18.3**) and are easy to identify prior to surgery due to their highly characteristic appearance (see Chapter 102). *Gliomas* are the second most common form of primary tumor accounting for 30% of all brain tumors (see Chapter 101). Glioblastoma multiforme is the most common form of glioma and account for 80% of all malignant brain tumors (**Fig. 18.4**). Anaplastic astrocytoma and oligodendrogliomas (**Fig. 18.5**) are lower grade tumors that show less prominent enhancement and no necrosis. Less common adult primary brain tumors, in order of frequency, are pituitary adenomas (**Fig. 18.6** and Chapter 104), nerve sheath tumors such as acoustic neuromas (see Chapter 106), and

FIGURE 18.1 Common causes of focal lesions in the brain based on location. Abbreviations: EBV, Epstein-Barr virus; GBM, glioblastoma; HSV, herpes simplex virus.

FIGURE 18.2 Metastatic small cell lung cancer. T1 magnetic resonance imaging of the brain shows multiple small enhancing metastatic nodules.

primary central nervous system lymphomas (PCNSLs) (Fig. 18.7 and Chapter 103). Table 18.1 outlines typical clinical features, imaging findings, and suggested ancillary testing in adult patients with suspected brain neoplasm.

In children, the most common primary brain tumors are gliomas (40%) including pilocytic astrocytoma (Fig. 18.8), embryonal tumors (15%) including medulloblastoma (Fig. 18.9), and ependymoma (~5%). Table 18.2 outlines typical clinical features, imaging findings, and suggested ancillary testing in children with suspected brain neoplasm (see also Chapter 150).

Cerebritis and Abscesses

Approximately 1,500 cases of brain abscess occur annually in the United States with an incidence of 0.3 to 1.3 cases per 100,000 of the population annually. Brain abscess (see Chapter 65) is most commonly caused by bacterial infection (Fig. 18.10), most commonly streptococci and staphylococci. Focal brain infection resulting in cerebritis or abscess can also be caused by *fungi* (Table 18.3). Among fungal infections, aspergillosis (Fig. 18.11), cryptococcosis (Fig. 18.12), candida, mucormycosis, and nocardia are most common in immunosuppressed patients. *Blastomyces*, histoplasmosis, and *Coccidioides* are most common in immunocompetent patients. The most common *parasitic* organisms that causes brain abscess are by far toxoplasmosis (Fig. 18.13) and cysticercosis (Fig. 18.14), although *Strongyloides* and *Entamoeba histolytica* are also common causes (see Chapter 68). *Tuberculosis* forms solid tuberculomas; after the caseous core liquefies, the tuberculoma becomes a tuberculous abscess (see Chapter 67). *Syphilis* can form gummas, cysticercosis can cause an inflammatory mass lesion when the cyst degenerates and dies, and

FIGURE 18.3 Large parasagittal olfactory groove meningioma strongly enhancing after contrast. Note the small cleft of cerebrospinal fluid noted along the left margin of the lesion (coronal image, A).

FIGURE 18.4 Glioblastoma multiforme. T1 magnetic resonance imaging shows central necrosis and ring enhancement with a nodular component extending into the center of the lesion.

viruses such as *herpes simplex 1* (see Chapter 69) can cause encephalitis complicated by acute swelling and inflammation of the affected temporal lobes (Fig. 18.15).

Other Inflammatory Lesions

Occasionally, noninfectious inflammatory processes can also cause mass lesions (Table 18.4). Most notoriously, *multiple sclerosis* (see Chapter 71) can form a large demyelinating mass lesion known as *Marburg variant* or *tumefactive multiple sclerosis* (Fig. 18.16). *Sarcoidosis* (see Chapter 75) can also present as an inflammatory intraparenchymal mass lesion. *Radiation necrosis* can present as a space-occupying mass lesion months to decades after prior radiation treatment (see Chapter 109).

FOCUSED HISTORY

Demographics

Age is an important factor for narrowing the differential diagnosis particularly for brain tumors. Children develop a very different set of brain tumors than do adults. Ependymoma affects the youngest children (high incidence among infants, toddlers, and preschoolers), followed by medulloblastoma and pilocytic astrocytoma (peak incidence between 5 and 10 y of age), oligodendroglioma (incidence peak at 40 y of age), anaplastic astrocytoma (incidence peak at 50 y of age), and glioblastoma (incidence peak at 65 y of age). The average age at diagnosis for pituitary adenomas and meningiomas straddle several decades, with pituitary adenomas primarily being diagnosed between age 20 and 50 years and meningiomas between age 40 and 60 years. Pituitary adenoma and meningiomas occur more commonly in women.

FIGURE 18.5 Fluid-attenuated inversion recovery **(A)** and T1 gadolinium-enhanced magnetic resonance **(B)** of a right frontal oligodendroglioma showing very little contrast enhancement and very little surrounding edema.

FIGURE 18.6 Pituitary macroadenoma. **A:** Hypointense on T1. **B:** Enhancing postcontrast.

FIGURE 18.7 Primary central nervous system lymphoma. **A:** Magnetic resonance imaging demonstrating restricted diffusion (bright) on diffusion-weighted imaging. **B:** Reduced apparent diffusion coefficient appears as a dark core. **C:** T1 imaging shows the tumor as isodense to normal brain with a surrounding ring of hypointense (darker) edema. **D:** Avid contrast enhancement with gadolinium on T1 imaging.

Time Course

Symptoms associated with abscesses tend to develop acutely to subacutely (with bacterial infections presenting more acutely and fungal infections more subacutely), whereas tumors present more subacutely to chronically based on their grade (for instance, glioblastoma tends to have a more subacute presentation as compared to meningiomas, which tend to have a more chronic presentations).

Past Medical History

It is essential to learn whether there was a past history of cancer and/or a history of immunosuppression. In patients with a history of systemic cancer, certain details are helpful in determining the likelihood that brain mass is a metastatic tumor. Small cell lung cancer metastasizes to the brain in about 50% of instances as opposed to 7% in cases of non–small cell lung cancer. In patients with prior breast cancer, HER2+/ER− status portends a higher likelihood of metastasis to the brain. The same applies for melanoma patients with head/neck/oral lesions and colorectal cancer patients with left-sided cancers. Regarding immunosuppression, a history of human immunodeficiency virus (HIV) is a major risk factor for PCNSL and toxoplasma infection (see Chapter 70), whereas neutropenia and steroid use is a major risk factor for aspergillosis, candida, mucormycosis, and nocardia infections.

Other important history elements include the following:

- A prior distant (usually 5-30 y prior) history of irradiation, which increases the long-term risk of meningiomas and malignant glioma
- A recent history of radiation treatment, which can lead to radiation necrosis
- A history of systemic sarcoidosis, which increases the likelihood that a brain mass is due to neurosarcoidosis
- Prior diagnoses of amenorrhea, galactorrhea, erectile dysfunction, infertility, or hyperthyroidism, which can be seen in pituitary adenomas

Social History

The social history portion of the interview may reveal HIV risk factors and/or risk factors for systemic cancers such as smoking history. Additionally, the patient's travel history may be helpful, particularly for identifying potential fungal and helminthic infections (see **Table 18.1**).

TABLE 18.1 Common Adult Brain Tumors

	Clinical Pearls	Imaging Features	CSF Studies and Systemic Workup
Metastatic tumors (in order of frequency)	Lung • Small cell lung cancer eventually metastasized to the brain in up to 50% of cases. Breast • HER2+/ER− receptor status portends a higher likelihood of metastasis to the brain. Melanoma • Head, neck, and primary oral lesions have a higher rate of metastasis. Renal • In up to 10% of patients, a new metastasis later develops in patients who were thought to have been cured of their primary tumor. Colorectal • Left-sided cancers are more likely to metastasize to the lung and brain, whereas right-sided tumors usually go to liver.	• Eighty percent of brain metastases occur in the cerebral hemispheres, 15% in the cerebellum, and 5% in the basal ganglia. • Metastases tend to localize to the gray-white junction location and the border zone between two major arterial distributions. • Brain metastases are multiple, approximately 50% of cases. • FLAIR imaging tends to reveal a large amount of associated vasogenic edema. • Magnetic resonance spectroscopy shows low NAA and creatine levels and elevated choline levels reflecting cell membrane and myelin turnover. • Gradient echo or SWI may demonstrate hemosiderin deposits in cancers that tend to hemorrhage (eg, melanoma, choriocarcinoma, renal cell, and thyroid cancer). Melanoma tends to be hyperdense on CT scan even in the absence of hemorrhage. On MRI, melanoma is hyperintense on T1 and hypointense on T2. • Colorectal metastases involve the cerebellum disproportionately.	More than 60% of patients with brain metastases will have a mass demonstrated on chest imaging that is either due to a primary lung cancer or lung metastases from a primary tumor elsewhere. Tests to consider when brain metastases are suspected: • Mammogram • Skin exam • Whole-body CT • Whole-body FDG-PET
Meningoma	• 35% of all primary brain tumors • 67% of cases occur in women. • Peak incidence, age 40-60 y	Dural based with dense, homogeneous enhancement • Isointense to hypointense on T1 • Isointense to hyperintense on T2 Anatomic predilection in order of frequency • Parasagittal • Convexity • Sphenoid ridge • Cerebellopontine angle • Olfactory groove Can elicit a bony reaction leading to hyperostosis of the overlying calvarium Calcification occurs in approximately 20% of cases.	None

Gliomas	• 30% of all primary brain tumors
	• Average age of diagnosis:
	  • Glioblastoma: 65 y
	  • Anaplastic astrocytoma: 50 y
	  • Oligodendroglioma: 40 y
	  • Anaplastic astrocytoma usually evolves from a lower grade astrocytoma.
		GBM
		• Causes extensive edema in the deep white matter
		• Enhances with gadolinium
		• Central areas of necrosis restrict on DWI (bright)
		• May have satellite lesions
		• Tumor often crosses the corpus callosum and anterior commissure.
		• Magnetic resonance spectroscopy: Cho/NAA ratio >2.2 is thought to be high grade.
		Anaplastic astrocytoma
		• Some contrast enhancement but no necrosis
		Oligodendroglioma
		• 40%-80% rate of calcification
		• Enhances in 50%-70%
		• Hemorrhage or cyst formation occurs in 20%.
		• Usually, there is little edema.
			Order lower extremity Doppler in patients with GBM. Ultimately, up to 25% of these patients suffer from venous thromboembolism during the first year of diagnosis.

Pituitary adenoma	10% of all primary brain tumors Classified as secretory (75%) and nonsecretory (25%) Prolactinoma • Amenorrhea • Galactorrhea • Gynecomastia • Erectile dysfunction or impotence • Infertility • Decrease in body hair	• Tends to be hypodense on CT • Microadenomas are generally hypointense on T1 and variable intensity on T2. • Adenomas do not enhance as much, and enhance later, than normal pituitary tissue. Dynamic contrast-enhanced MRI scans are best of delineate adenomas. • Macroadenoma are adenomas >10 mm. They have a propensity for hemorrhage and infarction (pituitary apoplexy).	Pituitary hormone panel • Prolactin • FSH • LH • Serum and 24-h urine cortisol levels • TSH and T_3/T_4 levels • Growth hormone Formal visual field testing and ophthalmologic evaluation are critical.

TABLE 18.1 Common Adult Brain Tumors *(continued)*

	Clinical Pearls	Imaging Features	CSF Studies and Systemic Workup
	Growth hormone–producing tumor • Gigantism • Acromegaly ACTH-producing tumors • Cushing syndrome TSH-producing tumors: • Primary hyperthyroidism	• Differential diagnosis • Rathke cyst: hyperintense on T1 and does not enhance • Craniopharyngioma: has cystic lesions and calcifications	Serum prolactin >200 μg/L with an adenoma >10 mm in size is diagnostic of a prolactinoma.
PCNSL	• Causes <5% of all primary brain tumors • Immunocompromised state (eg, HIV, transplant) is a major risk factor. • Among immunocompetent patients, the mean age of onset is 60 y and there is a slight male predominance.	Tends to be hypodense on CT MRI features • T1 hypointense and T2 hyperintense • DWI shows diffusion restriction (bright). Anatomic predilection • Periventricular white matter in 40% • Coating of ventricles in 40% • Deep gray matter nuclei/subcortical in 30% • Unusual multifocal distribution of tumor can occur. Diffusely enhancing in the immunocompetent patients; necrotic center can occur in immunocompromised patients. Spread across corpus callosum is suggestive of PCNSL. Masses tend to be <2 cm in patients with AIDS and >2 cm in non-AIDS patients.	Slit lamp examination reveals intraocular involvement in 15% of patients.

Abbreviations: ACTH, adrenocorticotropic hormone; Cho, choline; CSF, cerebrospinal fluid; CT, computed tomography; DWI, diffusion-weighted imaging; GBM, glioblastoma; FDG-PET, ^{18}F-fluorodeoxyglucose positron emission tomography; FLAIR, fluid-attenuated inversion recovery; FSH, follicle-stimulating hormone; HER2, human epidermal growth factor receptor 2; ER, estrogen receptor; HIV, human immunodeficiency virus; LH, luteinizing hormone; MRI, magnetic resonance imaging; NAA, *N*-acetylaspartate; PCNSL, primary central nervous system lymphoma; SWI, susceptibility-weighted imaging; T_3, triiodothyronine; T_4, thyroxine; TSH, thyroid-stimulating hormone.

TABLE 18.2 Common Pediatric Brain Tumors

	Clinical Pearls	Imaging Features	CSF Studies and Systemic Workup
Gliomas • Grade 1: pilocytic astrocytoma (see **Fig. 18.7**) • Grade 2: diffuse fibrillary astrocytoma	Two main types in children • Pilocytic astrocytoma • Diffuse fibrillary astrocytoma	• Pilocytic astrocytoma is predominately located in the cerebellum, optic pathways, and the dorsal brainstem. • Well circumscribed with a cystic component and an enhancing mural nodule • Diffuse fibrillary astrocytoma occurs more often supratentorially in deep midline structures and at the cervicomedullary junction. • Hypointense on T1 and hyperintense on T2 with varying degrees of enhancement	None
Medulloblastoma	Peak incidence is approximately between 5 and 10 y of age. Occurs in boys twice as often as girls	• Accounts for 50% of cerebellar tumors in children • Usually arise from the vermis then grow into the inferior or superior velum of the fourth ventricle • As opposed to ependymoma, medulloblastoma distorts the fourth ventricle. • Well circumscribed and hyperdense on CT. Up to 20% have calcification or cystic changes. • MRI often has diffusion restriction on DWI. Medulloblastoma tends to enhance to a moderate degree.	None
Ependymoma	Among pediatric patients, peak incidence among infants, toddlers, and preschoolers Another peak of incidence occurs in adults.	• Intracranial in 90% of pediatric patients (more often spinal in adults); most often localized to the floor of the fourth ventricle • Hypodense to isodense on CT • Calcification in up to 50%, cystic changes in 15%. Mild enhancement is the rule.	Spinal MRI is mandatory if cranial ependymoma is suspected. Spinal drop metastasis occurs in 5% of cases.

Abbreviations: CSF, cerebrospinal fluid; CT, computed tomography; DWI, diffusion-weighted imaging; MRI, magnetic resonance imaging.

FIGURE 18.8 Pilocytic astrocytoma with high signal intensity on fluid-attenuated inversion recovery imaging invading the midbrain.

Review of Systems

In the neurologic review of systems, a history of episodic changes in neurologic status may indicate either an epileptic seizure or an ICP plateau wave. Plateau waves are thought to be the result of a sudden increase in cerebral blood volume because of a sudden decrease in cerebral vascular resistance. Patients who have diminished blood flow absorption, either from an intracranial mass or leptomeningeal disease, are more likely to develop plateau waves than patients with normal cerebrospinal fluid (CSF) absorption.

Another important point of query should focus on prior episodes of focal neurologic deficits lasting days in distributions characteristic of multiple sclerosis attacks, such as unilateral vision loss, bilateral leg paresthesias, unilateral arm weakness/paresthesia, or double vision. This can point to tumefactive multiple sclerosis as the causative etiology.

Symptoms of subacute to chronic weight loss can point to an occult malignancy and when combined with fever and night sweats may indicate either a central nervous system lymphoma or tuberculosis, given the clinical context. History of galactorrhea or gynecomastia can raise concern for pituitary adenoma (see Chapter 104).

FOCUSED EXAM

In patients with focal mass lesions of the brain, the most important role of the exam is to assess for increased ICP and herniation. A pale optic disc, red desaturation, partial internuclear ophthalmoplegia, and increased leg reflexes with normal arm reflexes can all be indications of prior multiple sclerosis demyelinating episodes.

The next most important elements of the exam are found in the general exam. Patients with undetermined focal mass lesions require a careful lung, breast, skin, and gastrointestinal exam to assess for lumps or masses suggestive of malignancy.

The breast exam is also helpful to assess for gynecomastia, which can occur with pituitary adenoma. Skin examination may also be helpful to look for herpes simplex rashes, melanoma, Kaposi sarcoma, or peripheral manifestations of bacterial endocarditis such as Janeway lesions (nontender, small erythematous macular lesions on the palms or soles only a few millimeters in diameter that are indicative of infective endocarditis).

FIGURE 18.9 Medulloblastoma with distortion of the fourth ventricle and secondary hydrocephalus. **A:** Hypointense on T1. **B:** Nodular partial gadolinium enhancement within the tumor.

FIGURE 18.10 Left basal ganglia abscess. Bright on diffusion-weighted imaging **(A)** with restricted apparent diffusion coefficient **(B)** which appears dark, consistent with central necrosis. T2 images show hyperintense core and a hypointense ring **(C)** and postcontrast T1 image shows sharply demarcated thin rim enhancement postcontrast **(D)**.

TABLE 18.3 Common Infectious Etiologies of Mass Lesions

	Clinical Pearls	Imaging Features	CSF Studies and Systemic Workup

Bacterial abscess	Most abscesses in immunocompetent individuals are bacterial.
	Only 50% of patients have fever on initial presentation.
		• Characterized on T2 imaging as hyperintense core and hypointense ring, both of which restrict on DWI.
		• Ring enhancement with contrast imaging
		• MRS features
		  • Pyogenic aerobic abscess: Amino acids, lactate, and lipid are elevated.
		  • Pyogenic anaerobic abscess: Succinate and acetate are elevated.
		  • TB: Only lipid is elevated.
			• Blood cultures
			• Transesophageal echocardiography to detect a valvular vegetation
			• LP may reveal concurrent meningitis.

Tuberculoma	When the caseous core of the tuberculoma liquefies, a tuberculous abscess results.	CT appearance • Solid-enhancing, ring-enhancing, or mixed lesions • Occasionally, there is the "target sign," which is pathognomonic of TB: central calcification surrounded by a hypodense area with peripheral ring enhancement. MRI appearance • DWI: no abnormalities or can be bright with restriction like a bacterial abscess • T1: isointense in gray matter with a hyperintense ring • T2: noncaseating: hyperintense with nodular enhancement; caseating: iso-/hypointense with ring enhancement	• Tuberculin skin test is positive in up to 85% of patients. • Chest CT suggests pulmonary TB in 50%-80% of patients.
Gummatous neurosyphilis	Histology reveals that the central portion of the mass is necrotic material, and the peripheral region is infiltrated with plasma cells.	• CNS gummas can arise from the meningeal surfaces and extend directly into the brain or may arise directly from the parenchyma. • Presents as a ring-enhancing mass lesion	• Serum RPR and FTA-ABS • CSF VDRL
Viral encephalitis	HSV-1 only rarely causes a typical vesicular skin eruption in the setting of meningitis.	• DWI sequences on MRI are most sensitive for detecting tissue injury from encephalitis. • Herpes encephalitis can cause significant swelling and mass effect of the temporal lobes, mimicking tumor.	• CSF shows lymphocytic pleocytosis with normal or decreased glucose but can be normal.
Fungal	Immunocompromised • Aspergillosis • Cryptococcosis • Candida • Mucormycosis • Nocardia Immunocompetent • *Blastomyces* • *Histoplasma* • *Coccidioides*	• DWI shows restricted diffusion in the wall of a fungal abscess. Typically, the core does not show restriction (unlike in a bacterial abscess). • MRS can show increased trehalose, amino acids, and lactate. • Anatomic predilations • *Cryptococcus*: predominately in midbrain and basal ganglia • Coccidioidomycosis: predilection for the cerebellum • Mucormycosis: rim of soft-tissue thickness along the walls of the paranasal sinus. In some cases, bony destruction is present. • Nocardial: enhancing capsule containing multiple loculations • Aspergillosis: Aggressive forms manifest as meningoencephalitis; less aggressive forms manifest as solitary abscess or isolated granulomas.	• CSF shows lymphocytic predominance, although neutrophils may predominate early in the course. • Histoplasmosis causes CSF mononuclear pleocytosis. • *Coccidioides* may cause CSF eosinophilia.

(table continues on page 162)

TABLE 18.3 Common Infectious Etiologies of Mass Lesions *(continued)*

	Clinical Pearls	Imaging Features	CSF Studies and Systemic Workup
Helminthic infection	Travel history • Coenurosis cerebralis: sheep-raising areas North America/Europe/South America/Africa • Cysticercosis: endemic in Latin America, sub-Saharan Africa, and some regions of Asia • *Echinococcus granulosus*: reported in the Americas as well as Mediterranean countries • *Ascaris*: endemic in North America. Hosts are raccoons. • *Paragonimus*: Asia and South Pacific Islands • *Schistosoma japonicum*: Southeast Asia • *Spirometra*: Southeast Asia and the Americas • *Toxocara*: worldwide • *Trichinella*: worldwide • *Strongyloides*: Latin America, Caribbean, Africa, Asia	Cyst-forming • Coenurosis • Cysticercosis • *Echinococcus granulosus* Granuloma-forming • *Ascaris* • *Paragonimus* • *Schistosoma japonicum* • *Spirometra* • *Toxocara* • *Trichinella* Abscess • *Strongyloides*	CSF shows lymphocytic predominance except: • *Trichinella*, which demonstrates eosinophilic pleocytosis • *Strongyloides*, which demonstrates a neutrophilic pleocytosis
Protozoal infections	Immunosuppressed • *Acanthamoeba*: transmitted via swimming in freshwater pools • Toxoplasmosis: transmitted via food or congenitally • *Entamoeba histolytica* is associated with liver abscess.	Granulomatous encephalitis • *Acanthamoeba* • Toxoplasmosis Brain abscess • *Entamoeba histolytica*	• *Acanthamoeba* • CSF protein and glucose usually normal • Toxoplasmosis • The presence of IgG antibodies indicates prior exposure to the parasites and potential for reactivation.

Abbreviations: CNS, central nervous system; CSF, cerebrospinal fluid; CT, computed tomography; DWI, diffusion-weighted imaging; FTA-ABS, fluorescent treponemal antibody absorption; LP, lumbar puncture; HSV-1, herpes simplex virus 1; IgG, immunoglobulin G; MRI, magnetic resonance imaging; MRS, magnetic resonance spectroscopy; RPR, rapid plasma reagin; TB, tuberculosis; VDRL, Venereal Disease Research Laboratory.

FIGURE 18.11 Focal *Aspergillus* infection with little edema or mass effect. **A:** Bright on diffusion-weighted imaging with restriction. **B:** Dark on apparent diffusion coefficient suggesting necrosis. **C:** Heterogeneous coarse irregular enhancement on T1 with gadolinium.

FIGURE 18.15 Herpes simplex virus 1 encephalitis. Fluid attenuated inversion recovery image showing characteristic edema and swelling of right medial temporal lobe.

DIAGNOSIS

The diagnostic cornerstones for brain masses are imaging, lumbar puncture, and biopsy.

Imaging

Usually, a computed tomography (CT) scan (see Chapter 21) is the first radiographic study performed when a patient presents with a new neurologic symptom. Most focal brain lesions from tumor or abscess tend to be hypodense on CT. Admixture of heterogenous hyperdense signal usually represents hemorrhage into a tumor (typically glioblastoma multiforme) or less commonly an abscess. A homogenous hyperdense pattern can result from melanoma, medulloblastoma, or meningioma. Calcification, usually punctate, occurs in 40% of ependymomas, 20% of meningiomas, and 10% of medulloblastomas. Tuberculomas have a pathognomic "target sign" resulting from central calcification surrounded by a hypodense area with peripheral ring enhancement with IV contrast.

Although the CT scan can sometimes be helpful, an MRI (see Chapter 22) is always recommended unless there is a contraindication (eg, pacemaker). The important MRI sequences are diffusion-weighted imaging, fluid-attenuated inversion recovery (FLAIR), susceptibility-weighted imaging, T1 precontrast, and T1 postcontrast. Important imaging features are reviewed in Table 18.1.

Magnetic resonance spectroscopy is sometimes pursued, although its use is limited. Primary brain tumors are classically thought of as having an increased choline/*N*-acetylaspartate ratio (with ratio >2 suggestive of a high-grade tumor). In high-grade brain tumors, the surrounding FLAIR hyperintensity is thought to represent infiltrative tumor and also has an elevated

TABLE 18.4 Select Inflammatory Causes of Focal Brain Lesions

	Clinical Pearls	Imaging Features	CSF Studies and Systemic Workup
Sarcoidosis	• Sarcoidosis primarily occurs in the third and fourth decade. • Five percent of cases of systemic sarcoid have neurologic involvement.	• Intraparenchymal sarcoid masses may or may not enhance. • Nodules may be calcified, have an increased density, or be isodense and can occur throughout the brain parenchyma. • Nodular meningeal enhancement is common. • The nodules are not usually associated with edema. • Sarcoid nodules do not cavitate as frequently as tuberculosis.	• Chest CT • Gallium scan • Lacrimal gland biopsy • CSF and serum ACE activity
Whipple disease	• Mean age of onset is around 50 y. • Men are more commonly affected (80%). • In about 5% of the cases, the presentation is solely neurologic. In other cases, the small bowel is involved. • Granuloma formation is a delayed hypersensitivity to Whipple disease.	• The lesions are in the gray matter, in the basal part of the telencephalon, the hypothalamus, and the thalamus.	• *Tropheryma whippelii* PCR • Small bowel biopsy
Behçet disease	• Most common in the countries around the eastern shores of the Mediterranean, the Middle East, and Eastern Asia • Mean age of onset of neurologic symptoms is about 30 y of age. • Triad of recurrent genital ulcerations, skin or eye lesions, and meningitis	• Predilection for brainstem • Enhancement may occur as a ring or nodule.	• May also present as cortical vein thrombosis or isolated increased intracranial pressure
Tumefactive multiple sclerosis	• Mean age of onset is approximately 35 y of age. • The female-to-male prevalence is 1.2:1. • May have had previous neurologic symptoms isolated in space and time supportive of multiple sclerosis as a diagnosis	• Demyelinating lesion ≥2 cm in size • Incomplete ring enhancement open on the gray matter side of the lesion • Does not restrict on DWI • Magnetic resonance perfusion normal	• C-spine MRI

Abbreviations: ACE, angiotensin-converting enzyme; CSF, cerebrospinal fluid; CT, computed tomography; DWI, diffusion-weighted imaging; MRI, magnetic resonance imaging; PCR, polymerase chain reaction.

A,B C

FIGURE 18.16 Tumefactive multiple sclerosis. **A:** T1 image showing an intense hypodensity in the right parietal lobe. **B:** Gadolinium enhancement of the T1 image shows nodular ring enhancement in the core of the lesion, indicating acute inflammation and demyelination. **C:** Fluid attenuation inversion recovery image showing vasogenic edema infiltrating the surrounding cortex. Note also the periventrivcular lesions in the left hemisphere.

choline/*N*-acetylaspartate ratio, whereas in metastatic tumor, this surrounding FLAIR hyperintensity is thought to represent vasogenic edema and therefore has a low choline level. Additionally, lactate is thought to be very elevated in infections, although it can also be elevated in necrotic tumors, making the distinction somewhat difficult.

Brain positron emission tomography (PET) scans (see Chapter 23) can be helpful in distinguishing between radiation necrosis and recurrent tumor in that radiation necrosis is hypometabolic and recurrent tumor is hypermetabolic. The PET scan would also demonstrate increased metabolism in a high-grade tumor as opposed to a low-grade tumor. PET scans, however, have poor spatial resolution and are not useful for lesions smaller than 1 cm.

Whole-body CT scanning should be pursued whenever metastatic disease is being entertained.

Lumbar Puncture and Biopsy

Lumbar puncture (see Chapter 32) is an essential part of the neurologic examination in patients with intracranial mass lesions. CSF examination can reveal an infectious organism or the presence of malignant cells by cytology when central nervous system lymphoma, germ cell tumors, or carcinomatous meningitis is suspected.

For most primary brain tumors, however, lumbar puncture is not diagnostic, and when there is evidence of impending herniation, it is also not safe. CSF in the setting of cerebral abscess formation is often nondiagnostic. An important exception is in patients with HIV/AIDS who often can be infected with multiple opportunistic infections. In the case of encephalitis, whether viral, parasitic, or fungal, lumbar puncture is essential for establishing the diagnosis. Lumbar puncture is also routinely performed for the diagnosis of inflammatory masses resulting from sarcoidosis or multiple sclerosis.

The diagnostic method of choice for suspected malignancy or abscess is tissue biopsy or CT-guided drainage and culture, respectively (see Chapter 33). Eventually, the majority of patients with suspected brain tumor are diagnosed by pathologic examination of surgically resected tissue as the result of a diagnostic biopsy or as part of a partial debulking or gross total resection of the lesion.

INITIAL MANAGEMENT

If imaging reveals significant vasogenic edema, corticosteroids can be used to prevent further neurologic injury in the case of impending herniation or for symptomatic relief if the cause is felt to be tumor or abscess LEVEL 3.[5] Most often, the corticosteroid regimen is dexamethasone 10 mg IV as an initial dose followed by 4 to 6 mg every 6 hours LEVEL 2.[6] Use of steroids should be avoided when PCNSL is a main consideration because steroids can significantly lead to loss of the main histologic findings if the lesion is biopsied LEVEL 3.[7]

One situation in which lymphoma should be seriously considered is the case of the AIDS patient (CD4 <100/μL). In this case, the two most common etiologies of enhancing focal mass lesions are toxoplasmosis and PCNSL. **Figure 18.17** outlines an algorithm for managing to diagnosis, and **Table 18.5**

FIGURE 18.17 Algorithm for diagnosis and management of enhancing mass lesions in an AIDS patient. Abbreviations: CT, computed tomography; FDG-PET, ^{18}F-fluorodeoxyglucose positron emission tomography; MRI, magnetic resonance imaging; MRS, magnetic resonance spectroscopy; PCNSL, primary central nervous system lymphoma; SPECT, single-photon emission computed tomography.

TABLE 18.5 Imaging Differences Between Lymphoma and Toxoplasmosis

Lymphoma	Toxoplasmosis
Periventricular propensity	Basal ganglia propensity
Hypodense on T2/FLAIR	Hyperdense on T2/FLAIR
Single or multiple lesions	Lesions more numerous and smaller than lymphoma lesions
Does not tend to bleed except after steroids	May bleed pretreatment
Thallium spectroscopy and MR perfusion demonstrate increased uptake.	Thallium spectroscopy and MR perfusion demonstrate decreased uptake.
MR spectroscopy shows moderately elevated lactate and lipid and markedly elevated choline.	MR spectroscopy shows markedly elevated lactate and lipid.

Abbreviations: FLAIR, fluid-attenuated inversion recovery; MR, magnetic resonance.

outlines the imaging differences between lymphoma and toxoplasmosis. The standard approach is to withhold steroids unless absolutely necessary and proceed directly to biopsy in patients at high risk for PCNSL and otherwise to proceed with empiric therapy for toxoplasmosis. Therapy for toxoplasma encephalitis is oral pyrimethamine (adults: an initial loading dose of 50-200 mg followed by 25-50 mg/d; children: 2 mg/kg/d administered in divided doses every 12 h for 1-3 d, then 1 mg/kg daily or as divided doses every 12 h to a maximum of 25 mg/d) and sulfadiazine (adults: 6-8 g/d divided into four equal doses; children: 120 mg/kg/d in divided doses every 6 h in doses not to exceed the adult dose). Individuals allergic to sulfadiazine may be desensitized to sulfadiazine or alternatively treated with clindamycin 2,400 mg/d in three equal doses LEVEL 1.[8] Other treatment alternatives include atovaquone or azithromycin. In conjunction with the antitoxoplasmosis agents, folinic acid (5-10 mg/d) is concurrently administered to diminish bone marrow suppression. Regression of the lesion on follow-up magnetic resonance or CT confirms the diagnosis of toxoplasmosis. The total duration of therapy is at least 6 weeks and longer if the clinical response is incomplete at that time.

Another question that frequently arises in patients with new-onset mass lesions is whether to initiate antiepileptic treatment. Generally, unless the patient has had a seizure, antiepileptic treatment is not recommended LEVEL 1.[9,10] If the patient has significant increase in ICP with impending herniation, it is reasonable to initiate antiepileptic treatment even without a clinical history of a seizure. The thought in this circumstance is that by causing an increased cerebral metabolic demand, a seizure can lead to further increase in ICP and herniation.

LEVEL 1 EVIDENCE

19 Stupor and Coma

Jan Claassen and John C. M. Brust

KEY POINTS

1. Disorders of consciousness include abnormal arousal and awareness
2. Clinically disorders of consciousness are classified into coma, vegetative state/unresponsive wakefulness syndrome, and minimally conscious state
3. Classic herniation syndromes can be identified based on clinical examination
4. Impaired consciousness results from supra and infratentorial structural lesions, and metabolic or diffuse brain injury
5. Recovery from coma involves a variety of mechanisms that result in restored excitatory neurotransmission across long corticocortical, thalamocortical and thalamostriatal connections

INTRODUCTION

"Normal human consciousness consists of a serially, time-ordered, organized, restricted, and reflective awareness of self and the environment. Moreover, it is an experience of graded complexity and quantity." Schiff and Plum, *J Clin Neurophys*, 2000.

Philosophical and religious frameworks may influence definitions of consciousness. Consciousness is classically defined as awareness of self and the environment and requires both arousal (ie, wakefulness) and cognitive content (ie, thoughts and perceptions).

Coma is a state of unconsciousness that differs from sleep in that it represents a neurologic deficit and is not readily reversed. Brain metabolism is normal in sleep, and brain electrical activity progresses thorough organized stages of synchronized activity on electroencephalography (EEG). In coma, brain metabolism is abnormally reduced, and EEG activity progressively slows and becomes attenuated, with loss of normal reactivity to sensory stimuli.

DEFINITIONS

Coma is clinically defined by the neurologic examination, especially responses to external stimuli. Terms such as *lethargy*, *obtundation*, *stupor*, and *coma* usually depend on the patient's response to normal verbal stimuli, shouting, shaking, or pain. Some of these terms such as obtundation are not rigidly defined, and it is useful to record both the response and the stimulus that elicited it. Occasionally, the true level of consciousness may be difficult or impossible to determine due to coexisting behavioral disturbances (ie, catatonia in severe depression) or neurologic deficits (ie, akinesia plus aphasia) that blunt responses to stimuli.

The chronicity of the impaired mental status differentiates acute disorders of consciousness such as stupor and coma from their long-term correlates: the chronic disorders of consciousness known as *unresponsive wakefulness syndrome* (UWS) or *vegetative state* (VS) and minimally conscious state (MCS). UWS/VS is characterized by arousal (ie, eyes open) without awareness (ie, lack of the ability to follow verbal commands).

MCS differs from VS in that the patient demonstrates low-level awareness (eg, visual pursuit or inconsistent command following) with the presence or absence of language function distinguishing between MCS plus and minus, respectively. Cognitive motor dissociation represents a state in which task specific brain activity can be detected using functional magnetic resonance imaging (MRI) or EEG in behaviorally unresponsive patients.

Induced states of altered consciousness such as those seen during general anesthesia or with sedation in the intensive care unit (ICU) share some similarities with coma induced by brain injury and may confound the assessment of comatose patients. Sedatives are frequently required in critically ill patients to facilitate ventilator management or to manage pain or agitation. *Accurate neurologic assessments of the level of consciousness in the ICU are challenging in the context of these confounders, and sedation can not safely be interrupted in all patients (ie, risk of elevated intracranial pressure* [ICP]). For this reason, short-acting continuous infusion agents such as propofol, midazolam, or fentanyl are preferred, and novel ways of assessing consciousness such as EEG are investigated.

Confusional state and *delirium* are terms that refer to a state of inattentiveness, altered cognitive content, and sometimes hyperactivity, rather than to a decreased level of arousal; these states may be seen in the context of emergence from coma.

NEUROANATOMY

Widespread areas spanning the brainstem (particularly the reticular activating system), basal ganglia (particularly central thalamic nuclei that diffusely project with striatopallidal modulation), and the cortex are fundamental to support a conscious state. Location for classic structural brain lesions associated with stupor and coma have been derived from lesion studies and more recently confirmed and expanded based on structural and functional brain imaging studies such as diffusion tensor and resting state MRI (Fig. 19.1).

MANAGEMENT STRATEGY

A suggested algorithm for the initial management of new-onset coma is shown in Figure 19.2.

Initial Resuscitation

Initial management of the comatose patient should always focus on the airway, breathing, and circulation. Assuring a patent airway, securing adequate ventilation, and restoring or

FIGURE 19.1 Anatomy of coma. Classic brain lesions that cause coma include those located diffuse bihemispheric **(A)**, diencephalic **(B)**, paramedian caudal midbrain and caudal diencephalic **(C)**, high pontine and lower midbrain paramedian tegmental regions **(D)**, and pontine **(E)**. (From Posner JB, Saper CB, Schiff ND, Claassen J. *Plum and Posner's Diagnosis and Treatment of Stupor and Coma*. 5th ed. New York, NY: Oxford University Press; 2019.)

FIGURE 19.2 Management algorithm for new-onset coma. Abbreviations: CT, computed tomography; EEG, electroencephalography; IV, intravenous; MRI, magnetic resonance imaging.

maintaining circulation should take precedence as it does with any critically ill patient. Vascular access needs to be obtained as soon as possible and may include central venous access and large-bore peripheral access. Detection and treatment of immediately life-threatening systemic conditions may include stopping a hemorrhage; supporting the circulation by administration of fluids, blood products, or pressors; intubation when necessary (eg, to prevent aspiration in a patient who is vomiting); and obtaining an electrocardiogram to detect dangerous arrhythmias. Fingerstick glucose should be obtained immediately and if in doubt, 50% dextrose should be given intravenously with parenteral thiamine. (Administering glucose alone to a thiamine-deficient patient can precipitate Wernicke-Korsakoff syndrome.) When opioid overdose is a possibility, naloxone hydrochloride (Narcan) 0.4 mg intravenous is given. If trauma is suspected, damage to internal organs and cervical fracture should be assumed until radiographs determine otherwise, and emergency ultrasound scanning (ie, focused assessment with sonography for trauma) or other imaging has ruled out major internal bleeding or organ injury.

History and General Physical Examination

The next step is to localize and identify the underlying cause of coma. A history is obtained from whoever accompanies the patient, including emergency medical service providers. **Table 19.1** lists a number of practical pearls to look for that can aid in the diagnosis of nontraumatic coma. Order an emergent EEG to evaluate for nonconvulsive seizures or status epilepticus if even minor involuntary facial or extremity twitching is observed or the imaging and laboratory studies do not conclusively identify the impairment of consciousness.

Focused Neurologic Examination

In their classic monograph, Plum and Posner divided the causes of coma into supra- and infratentorial structural lesions and diffuse or metabolic diseases. By concentrating on motor responses to stimuli, respiratory patterns, pupils, and eye movements, the clinician can usually localize the cause and identify the category of coma. This is helpful to guide the immediate approach to the patient because the majority of patients have nonstructural causes of coma. However, immediate computed tomography (CT) imaging should not be delayed because immediate surgical interventions may be lifesaving in patients with structural lesions, such as the placement of an external ventricular drainage catheter in patients with hydrocephalus.

Motor Responses

The patient is observed to assess respiration, limb position, and spontaneous movements. Myoclonus or seizures may be subtle (eg, twitching of one or two fingers or the corner of the mouth). More florid movements, such as facial grimacing, jaw gyrations, tongue protrusion, or complex repetitive limb movements, may defy ready interpretation. Asymmetric movements or postures may signify either focal seizures or hemiparesis.

Assessment of motor tone is crucial in the examination of coma. Asymmetry of muscle tone suggests a structural lesion, but it is not always clear which side is abnormal. *Gegenhalten*, or *paratonia*, is variable resistance to passive movement that often increases with the velocity of the movement; it is attributed to diffuse forebrain dysfunction and is often accompanied by a grasp reflex. *Rigidity* is present throughout the entire range of

TABLE 19.1 Practical Pearls in the Physical Examination of the Comatose Patient

System	Positive Finding
Body temperature	• Fever (implies infection or heatstroke) • Hypothermia (cold exposure, sepsis, cardiac arrest, hypothyroidism, hypoglycemia)
Peripheral pulses	• Asymmetry of pulses suggests dissecting aortic aneurysm.
Head and scalp	• External signs of trauma (eg, mastoid ecchymoses consistent with Battle sign) • Ears and nose are examined for blood or CSF.
Skin, nails, and mucous membranes	• Pallor • Cherry redness (carbon monoxide poisoning) • Cyanosis • Jaundice • Sweating • Uremic frost • Myxedema (dry, flaky, cool skin) • Petechiae • Dehydration • Decubiti • Signs of trauma
Breath	• Acetone • Alcohol • Fetor hepaticus
Optic fundi	• Papilledema (suggests elevated ICP), hypertensive or diabetic retinopathy, retinal ischemia • Roth spots (suggests endocarditis) • Subhyaloid hemorrhages (suggests subarachnoid hemorrhage)
Neck	• Resistance to passive neck flexion but not to turning suggests meningitis, subarachnoid hemorrhage, or foramen magnum herniation. • Resistance to manipulation in all directions suggests bone or joint disease, including fracture.
Urinary or fecal incontinence	• May signify an unwitnessed seizure, especially in patients who subsequently awaken

Abbreviations: CSF, cerebrospinal fluid; ICP, intracranial pressure.

movement, is often seen in combination with cogwheeling, and usually indicates basal ganglia dysfunction (eg, parkinsonism) or symptomatic hydrocephalus. *Spasticity* has a characteristic "catch" midway through passive movement and indicates corticospinal pathway dysfunction. Acute transtentorial herniation often produces exaggerated lower extremity spasticity and clonus.

Motor responses to stimuli may be appropriate, inappropriate, or absent. Even when patients are not fully awake, they may be roused to follow simple commands. Some patients who respond only to noxious stimuli (eg, pressure on the sternum or supraorbital bone; pinching the neck or limbs; or squeezing muscle, tendon, or nail beds) may make voluntary avoidance responses. The terms *decorticate* and *decerebrate* posturing are physiologic misnomers but refer to stereotyped hypertonic flexion or extension in response to noxious stimuli (Fig. 19.3). In *decorticate rigidity*, the arms are flexed, adducted, and internally rotated, and the legs are extended; in *decerebrate rigidity*, the arms and legs are all extended. These postures are most often associated with cerebral hemisphere disease, including hypoxic-ischemic or metabolic encephalopathy, but may follow upper brainstem lesions or transtentorial herniation as well (see later section for a discussion of herniation syndromes). Flexor posturing generally implies a more rostral lesion and has a better prognosis than extensor posturing, but the pattern of response may vary with different stimuli, or there may be flexion of one arm and extension of the other. When these postures seem to occur spontaneously, there may be an unrecognized stimulus (eg, airway obstruction or bladder distention). With continuing rostrocaudal deterioration, there may be extension of the arms and flexion of the legs until, with lower brainstem destruction, there is flaccid unresponsiveness. However, lack of motor response to any stimulus should always raise the possibility of limb paralysis caused by cervical trauma, Guillain-Barré neuropathy, or the locked-in state.

FIGURE 19.3 Decerebrate or extensor posturing **(A)** and decorticate or flexor posting **(B)**.

Respiration

In Cheyne-Stokes respiration (CSR), periods of hyperventilation and apnea alternate in a crescendo-decrescendo fashion. The hyperpneic phase is usually longer than the apneic, so arterial gases tend to show respiratory alkalosis. CSR occurs with bilateral cerebral disease or metabolic encephalopathy. It usually signifies that the patient is not in imminent danger. Long-cycle CSR, with brief periods of apnea occurring every 1 to 2 minutes, is a stable breathing pattern and does not imply impending respiratory arrest. Conversely, "short-cycle CSR" (*cluster breathing*) with less smooth waxing and waning is often an ominous sign of a posterior fossa lesion or dangerously elevated ICP.

Sustained hyperventilation is usually due to metabolic acidosis, pulmonary congestion, hepatic encephalopathy, or during acute herniation (see Fig. 19.3). Rarely, it is the result of a lesion in the rostral brainstem. *Apneustic breathing*, consisting of long inspiratory pauses, is seen with pontine lesions, especially infarction; it occurs infrequently with metabolic coma or transtentorial herniation.

Respiration having a variably irregular rate and amplitude (*ataxic breathing*) indicates medullary damage and may progress to apnea, which also occurs abruptly in acute posterior fossa lesions. Loss of automatic respiration with preserved voluntary breathing (*Ondine curse*) occurs with medullary lesions; as the patient becomes less alert, apnea may be fatal. Other ominous respiratory signs are end-expiratory pushing (eg, coughing) and "fish-mouthing" (ie, lower jaw depression with inspiration). Stertorous breathing (ie, inspiratory noise) is a sign of airway obstruction.

Pupils

Pupillary abnormalities in coma may reflect an imbalance between input from the parasympathetic and sympathetic nervous systems or lesions of both. Although many people have slight pupillary inequality, anisocoria should be considered pathologic in a comatose patient. Retinal or optic nerve damage does not cause anisocoria, even though there is an afferent pupillary defect. Parasympathetic lesions (eg, oculomotor nerve compression in uncal herniation or after rupture of an internal carotid artery aneurysm) cause pupillary enlargement and, ultimately, full dilation with loss of reactivity to light. Sympathetic lesions, either intraparenchymal (eg, hypothalamic injury or lateral medullary infarction) or extraparenchymal (eg, invasion of the superior cervical ganglion by lung cancer), cause Horner syndrome with miosis. With involvement of both systems (eg, midbrain destruction), one or both pupils are in midposition and are unreactive. Small but reactive pupils following pontine hemorrhage are the result of damage to descending intra-axial sympathetic pathways.

With few exceptions, metabolic disease does not cause unequal or unreactive pupils. Fixed, dilated pupils after diffuse anoxia-ischemia denote a bad prognosis. Anticholinergic drugs, including glutethimide, amitriptyline, and antiparkinsonian agents, abolish pupillary reactivity. Hypothermia and severe barbiturate intoxication may cause not only fixed pupils but also a reversible picture that mimics brain death. Bilateral or unilateral pupillary dilation and nonreactivity may accompany (or briefly follow) a seizure. In opiate overdose, miosis may be so severe that a very bright light and a magnifying glass are necessary to detect reactivity. Some pupillary abnormalities are local in origin (eg, trauma or synechiae).

Eyelids and Eye Movements

Spontaneous blinking may occur with or without purposeful limb movements. Eyes that are conjugately deviated away from hemiparetic limbs indicate a destructive cerebral lesion on the side toward which the eyes are directed. Eyes turned toward paretic limbs may indicate a pontine lesion, an adversive seizure, or the wrong-way gaze paresis of thalamic hemorrhage. Eyes that are dysconjugate while at rest may indicate paresis of individual muscles, internuclear ophthalmoplegia, or preexisting tropia or phoria.

When the brainstem is intact, the eyes may rove irregularly from side to side with a slow, smooth velocity; jerky movements suggest saccades and relative wakefulness. Repetitive smooth excursions of the eyes first to one side and then to the other, with 2- to 3-second pauses in each direction (*periodic alternating* or *ping-pong gaze*), may follow bilateral cerebral infarction or cerebellar hemorrhage with an intact brainstem.

If cervical injury has been ruled out, oculocephalic testing (the *doll's eyes maneuver*) is performed by passively turning the head from side to side; with an intact reflex arc (vestibular system → brainstem → eye muscles), the eyes move conjugately in the opposite direction (Fig. 19.4). A more vigorous stimulus is produced by irrigating each ear with 30 to 60 mL of ice water. A normal, awake person with head elevated at 30 degrees has nystagmus with the fast component in the direction opposite the ear stimulated, but a comatose patient with an intact reflex arc has deviation of the eyes toward the stimulus, usually for several minutes. Simultaneous bilateral irrigation causes vertical deviation, upward after warm water and downward after cold water.

Oculocephalic or caloric testing may reveal intact eye movements, gaze palsy, individual muscle paresis, internuclear ophthalmoplegia, or no response. Cerebral gaze paresis may often be overcome by these maneuvers, but brainstem gaze palsies are usually fixed. Complete ophthalmoplegia may follow

FIGURE 19.4 **A:** Doll's eye maneuver (oculocephalic reflex): With intact brainstem (cranial nerves III through VIII), the eyes remain relatively stationary and move opposite to the direction of head turning. **B:** Cold caloric test (oculovestibular reflex): With intact brainstem, cold water in the auditory canal results in tonic conjugate eye deviation toward the cold ear.

either extensive brainstem damage or metabolic coma, but except for barbiturate or phenytoin poisoning, eye movements are preserved early in metabolic encephalopathy. Unexplained disconjugate eyes indicate a brainstem or cranial nerve lesion (including abducens palsy due to increased ICP).

Downward deviation of the eyes occurs with lesions in the thalamus or midbrain pretectum and may be accompanied by pupils that do not react to light (*Parinaud syndrome*). Downward eye deviation also occurs in metabolic coma, especially in barbiturate poisoning and after a seizure. Skew deviation, or vertical divergence, follows lesions of the cerebellum or brainstem, especially the pontine tegmentum.

Retraction and convergence nystagmus may be seen with midbrain lesions, but spontaneous nystagmus is rare in coma. *Ocular bobbing* (ie, conjugate brisk downward movements from the primary position) usually follows destructive lesions of the pontine tegmentum (when lateral eye movements are lost). Preservation of voluntary vertical eye movements with loss of lateral eye movements and quadriplegia is consistent with *locked-in syndrome*. Unilateral bobbing (ie, nystagmoid jerking) signifies pontine disease.

DIAGNOSTIC TESTS

CT or MRI should be promptly performed whenever coma is unexplained. Unless meningitis is suspected, imaging should precede lumbar puncture. If imaging is not readily available, a spinal tap is cautiously performed with a 20- or 22-gauge needle. If imaging reveals frank, transtentorial, or foramen magnum herniation, the comparative risks of performing a lumbar puncture or of treating for meningitis without cerebrospinal fluid confirmation must be weighed individually for each patient.

Other emergency laboratory studies include serum levels of glucose, sodium, calcium, and blood urea nitrogen or creatinine; determination of arterial pH and partial pressures of oxygen and carbon dioxide; and blood or urine toxicology testing (including testing serum levels of sedative drugs and ethanol). Blood and cerebrospinal fluid should be cultured and liver function studies and other serum electrolyte levels determined. The use of coagulation studies and other metabolic tests is based on the index of suspicion.

The EEG may distinguish coma from psychic unresponsiveness or complete locked-in state. In metabolic coma, the EEG is typically abnormal, and early in the course, it may be a more sensitive indicator of abnormality than the clinical state of the patient. The EEG may also reveal asymmetries or evidence of clinically unsuspected seizure activity. Patients without clinical seizures can demonstrate repetitive electrographic seizures or continuous spike-and-wave activity; conversely, patients with subtle motor manifestations of seizures sometimes display only diffuse electrographic slowing. Distinguishing true status epilepticus from myoclonus (common after anoxic-ischemic brain damage) is often difficult, both clinically and electrographically; if any doubt exists, anticonvulsant therapy should be instituted.

COMA PRESENTATIONS AND TREATMENT

Many structural and nonstructural pathologies can result in impaired consciousness, necessitating a structured diagnostic approach with a broad differential. For rapid efficient communication between providers, generalizable scales such as the Full Outline of UnResponsiveness score may be helpful (**Fig. 19.5**). A more commonly used alternative is the Glasgow Coma Scale (**Table 19.2**). The most accurate scale to quantify consciousness and predict recovery is the Coma Recovery Scale-Revised, which allows reliable diagnosis of the prognostically significant MCS.

Coma From Supratentorial Herniation Syndromes

Coma may result from bilateral cerebral damage or from sudden large unilateral lesions that functionally disrupt the contralateral hemisphere (*diaschisis*). Herniation syndromes result from mass lesions that shift the brain out of its normal position. CT studies indicate that with acute hemisphere masses, early depression of consciousness correlates more with lateral brain displacement than with downward transtentorial herniation. The different types of herniation syndromes are described in (**Table 19.3**). It is important to keep in mind that different herniation syndromes can occur in a sequence or combination. For instance, an expanding hemispheric mass lesion resulting in lateral brain displacement may initially produce subfalcine herniation, followed by uncal herniation as a combination of downward and lateral displacement ensues.

Subfalcine herniation results from lateral displacement of the brain from mass lesions that are positioned rostrally in the cranial vault, at the level of the lateral ventricles or above (**Fig. 19.6**). *Transtentorial herniation* can result from lateralized (uncal) or bilateral (central) downward displacement. In *uncal herniation*, brainstem signs are initially lateralized. Typically, there is early compression of the oculomotor nerve by the inferomedial temporal lobe with ipsilateral pupillary enlargement. Alertness may not be altered until the pupil is dilated, at which point there may be an acceleration of signs, with unilaterally and then bilaterally fixed pupils and oculomotor palsy, hyperventilation or ataxic breathing, and progressive unresponsiveness. Typically, a lateralized motor deficit progresses to symmetric and bilateral flexor and then extensor posturing because the most caudal level of injury progresses to the upper brainstem. During the downward course of transtentorial herniation, there may be hemiparesis ipsilateral or oculomotor nerve compression contralateral to the cerebral lesion, which can be attributed to compression of the contralateral midbrain peduncle against the tentorial edge (*Kernohan notch*). Aqueduct obstruction and posterior cerebral artery compression may further raise supratentorial pressure. If the process is not halted, there is progression to deep coma, apnea, bilaterally unreactive pupils, ophthalmoplegia, and eventually, circulatory collapse, and brain death.

In *central transtentorial herniation* (as in thalamic hemorrhage), consciousness is rapidly impaired, and abnormalities of brainstem reflexes progress in rostrocaudal fashion. Pupils initially are of normal or small diameter and react to light, lateral eye movements and corneal reflexes are preserved, and bilateral spasticity progresses to flexor posturing. This stage is referred to as *diencephalic syndrome* because the level of injury is localized to the level of the thalamus. As herniation progresses, the pupils become fixed in midposition (midbrain pupils); this is followed by loss of pontine level brainstem reflexes (corneal and oculocephalic) and sometimes by pinpoint unreactive pupils (pontine pupils). Eventually, only medullary function remains (gag and cough), and after these are abolished brain death ensues.

The major lesions causing transtentorial herniation are traumatic (eg, epidural, subdural, or intraparenchymal hemorrhage), vascular (eg, ischemic or hemorrhagic), infectious (eg, abscess or granuloma,

FIGURE 19.5 **A:** Eye response. *E4*, eyelids open or opened, tracking, or blinking to command; *E3*, eyelids open but not tracking; *E2*, eyelids closed but open to loud voice; *E1*, eyelids closed but open to pain; *E0*, eyelids remain closed with pain. **B:** Motor response. *M4*, thumbs-up, fist, or peace sign; *M3*, localizing to pain; *M2*, flexion respónse to pain; *M1*, extension response to pain; *M0*, no response to pain or generalized myoclonus status. **C:** Brainstem reflexes. *B4*, pupil and corneal reflexes present; *B3*, one pupil wide and fixed; *B2*, pupil or corneal reflexes absent; *B1*, pupil and corneal reflexes absent; *B0*, absent pupil, corneal, and cough reflex. **D:** Respiration pattern. *R4*, not intubated, regular breathing pattern; *R3*, not intubated, Cheyne-Stokes breathing pattern; *R2*, not intubated, irregular breathing; *R1*, breathes above ventilatory rate; *R0*, breathes at ventilator rate or apnea. (From Wijdicks EFM, Bamlet WR, Maramattom BV, Manno EM, McClelland RL. Validation of a new coma scale: the FOUR score. *Ann Neurol*. 2005;58[4]:585-593.)

TABLE 19.2 Glasgow Coma Scale[a,b]

Eye opening	Spontaneous	4
	To voice	3
	To pain	2

	None	1
Total score		3-15

[a]Although a total score can be calculated, proper notation of the Glasgow Coma Scale involves delimitation of the three subscores. For instance, e3 m5 v3 applies to a patient who opens eyes to voice, localizes to pain, and is capable of uttering words but not sentences.
[b]From Teasdale G, Jennett B. Assessment of coma and impaired consciousness. A practical scale. *Lancet*. 1974;2(7872):81-84.

including lesions associated with AIDS), and neoplastic (primary or metastatic). CT or MRI locates and often defines the lesion.

Coma From Infratentorial Structural Lesions

Infratentorial structural lesions may compress or directly destroy the brainstem. Such lesions may also cause brain herniation either transtentorially upward (with midbrain compression) or downward through the foramen magnum, with distortion of the medulla by the cerebellar tonsils. Abrupt tonsillar herniation causes apnea and circulatory collapse; coma is then secondary, for the medullary reticular formation has little direct role in arousal. In coma, *primary infratentorial structural lesions* are suggested by bilateral weakness or sensory loss, crossed cranial nerve and long-tract signs, miosis, loss of lateral gaze with preserved vertical eye movements, dysconjugate gaze, ophthalmoplegia, short-cycle CSR, and apneustic or ataxic breathing. The clinical picture of pontine hemorrhage (ie, sudden coma, pinpoint but reactive pupils, and no eye movement) is characteristic, but if the sequence of signs in a comatose patient is unknown, it may not be possible to tell whether the process began supratentorially or infratentorially without the use of imaging. Infrequent brainstem causes of coma include multiple sclerosis and central pontine myelinolysis.

TABLE 19.3 Herniation Syndromes

Types	Mechanism of Herniation/Complications
Subfalcine	• Mechanism: lateral shifting displacement of the brain by a compartmentalized hemispheric mass lesion at the level of the ventricles or above • Classic causes: malignant MCA infarction, acute subdural or epidural hematoma • Imaging: midline shift with ipsilateral widening of the perimesencephalic cisterns • Clinical: contralateral hemiparesis progressing to bilateral motor posturing and coma, with late ipsilateral CN III palsy due to stretching of the oculomotor nerve • Complications: delayed ipsilateral ACA pericallosal infarction due to compression against the falx
Central transtentorial	• Mechanism: downward displacement of the brain by a bilateral supratentorial mass lesion, with craniocaudal pressure on diencephalon with downward displacement • Classic causes: massive bilateral intraventricular hemorrhage leading to acute obstructive hydrocephalus, massive global cerebral edema • Imaging: bilateral loss of the perimesencephalic cisterns and downward displacement of the midbrain tectum into the posterior fossa • Clinical: early Parinaud syndrome (loss of upgaze and convergence, retraction nystagmus) followed by rostrocaudal loss of brainstem reflexes associated with progression from decorticate to decerebrate posturing • Complications: stretching of small penetrating vessels leading to diencephalic and brainstem infarction, sometimes pituitary damage • Less common dorsal pressure leading to Parinaud syndrome (limitation of upward eye movements, usually with impairment of pupillary light reflex and difficulty with convergence)
Uncal transtentorial	• Mechanism: displacement of medial temporal lobe over free tentorial edge by a temporal lobe mass lesion or during the late stages of lateral and downward herniation • Classic causes: intracerebral mass lesions, for example, intracerebral hematoma, subdural hematoma, brain tumor • Imaging: prominent medial displacement of the uncus into the tentorial notch • Clinical: early ipsilateral dilated pupil due to CN III compression and ipsilateral or contralateral hemiparesis/posturing • Complications: trapping of the contralateral lateral ventricle due to compression of the third ventricle and aqueduct; compression of posterior cerebral arteries with resultant infarction
Tonsillar	• Mechanisms: displacement of cerebellar tonsils into the foramen magnum → compression of medulla and fourth ventricle • Classic cause: acute cerebellar ICH or rapidly expanding tumor • Imaging: herniation of cerebellar tonsils into the foramen magnum at level of the medulla • Clinical: impaired respiratory and cardiac function, neck stiffness, flaccid paralysis, and coma • Complications: secondary obstructive hydrocephalus due to obstruction of the fourth ventricle
Upward herniation	• Mechanisms: displacement of superior cerebellar vermis upward leading to compression of dorsal mesencephalon, blood vessels, and aqueduct • Classic cause: acute cerebellar ICH or rapidly expanding tumor • Imaging: cerebellar mass lesion with effacement of quadrigeminal cistern and upward displacement of midbrain tectum • Clinical: impaired consciousness, loss of pupillary and oculocephalic reflexes • Complications: secondary obstructive hydrocephalus due to obstruction of the cerebral aqueduct

Abbreviations: ACA, anterior cerebral artery; CN, cranial nerve; ICH, intracranial hemorrhage; MCA, middle cerebral artery.

FIGURE 19.6 Herniation syndromes.

Coma From Metabolic or Diffuse Brain Disease

In metabolic, diffuse, or multifocal encephalopathy, cognitive and respiratory abnormalities occur early; there is often tremor, asterixis, or multifocal myoclonus. Gegenhalten, frontal release signs (eg, snout, suck, or grasp), and flexor or extensor posturing may occur. Except in anoxia-ischemia and anticholinergic intoxication, the pupils remain reactive. The eyes may be deviated downward, but the presence of sustained lateral deviation or disconjugate eyes argues against the diagnosis of a metabolic disturbance. Metabolic disease, however, may cause both focal seizures and lateralizing neurologic signs, often shifting but sometimes persisting (as in hypoglycemia and hyperglycemia).

Arterial blood gas determinations are especially useful in diagnosing metabolic coma. Of the diseases listed in **Table 19.4**, psychogenic hyperventilation is more likely to cause delirium than stupor but may coexist with hysterical coma. Cognitive change associated with metabolic alkalosis is usually mild. Metabolic and diffuse brain diseases causing coma are numerous, but the diversity is not overwhelming. Most entities listed in **Table 19.5** are described in other chapters.

HYSTERIA AND CATATONIA

Hysterical (conversion) unresponsiveness is rare. Clinically indistinguishable from malingering, it is usually associated with closed eyes, eupnea or tachypnea, and normal pupils. The eyelids may resist passive opening and, when released, may close abruptly rather than with smooth descent; lightly stroking the eyelashes causes lid fluttering. The eyes do not slowly rove but move with saccadic jerks, and ice water caloric testing causes nystagmus rather than sustained deviation. The limbs usually offer no resistance to passive movement, yet demonstrate normal tone. Unless organic disease or drug effect is also present, the EEG pattern is one of normal wakefulness.

Catatonia is a behavioral disturbance characterized by wakeful unresponsiveness with minimal or no spontaneous purposeful behavior or speech. It is most commonly associated with depression, schizophrenia, toxic psychosis, or other brain diseases. There may be akinetic mutism, grimacing, rigidity, posturing, catalepsy, or excitement. Respirations are normal or rapid, pupils are large but reactive, and eye movements are normal. The EEG is usually normal.

LOCKED-IN SYNDROME

Infarction, hemorrhage, or rarely, central pontine myelinolysis may destroy the basis pontis, producing total paralysis of the lower cranial nerve and limb muscles, with preserved alertness and respiration. At first glance, the patient appears unresponsive, but examination reveals voluntary vertical eye movements, including blinking. (Even with facial paralysis, inhibition of the levator palpebrae may produce partial eye closure.) Communication is possible with the use of purposeful blinking or eye movements to indicate "yes," "no," or in response to letters.

VEGETATIVE STATE AND MINIMALLY CONSCIOUS STATE

Persistent impairment of consciousness in the postacute hospitalization phase is categorized into MCS and UWS, also known as *vegetative state*. Patients with UWS have sleep-wake cycles,

TABLE 19.5 Diffuse Brain Diseases or Metabolic Disorders That Cause Coma

The internal milieu: an overview of cerebral metabolism and the environment necessary to maintain normal neuronal function
• Cerebral blood flow, oxygen, and glucose utilization • Ionic environment in the brain and cortical spreading depolarization • Synaptic environment in the brain and seizures
Disorders of the internal milieu: lack of substrate
• Cerebral hypoxia and ischemia • Hyperoxia • Hypoglycemia • Cofactor deficiency • Mitochondrial disorders
Disorders of the internal milieu: ionic and osmotic environment
• Hyponatremia • Hypernatremia • Hypercalcemia • Hypocalcemia • Metabolic acidosis (disorders of systemic acid-base balance) • Hyperglycemic hyperosmolar state
Disorders of the internal milieu: hormonal and temperature
• Hypothyroidism • Hyperthyroidism • Adrenal gland • Hypothermia • Hyperthermia
Disorders of the internal milieu: electrical environment
• Seizure disorders • Cortical spreading depression
Disorders of the internal milieu: abnormal CSF pressure or constituents
• Intracranial hypertension • Intracranial hypotension • Subarachnoid hemorrhage • Acute bacterial meningitis • Chronic bacterial or fungal meningitis • Viral meningitis versus encephalitis • Acute viral encephalitis • Carcinomatous meningitis
Disorders of endogenous toxins
• Hypercarbia • Hepatic encephalopathy • Renal failure • Pancreatic encephalopathy • Systemic septic encephalopathy • Autoimmune disorders: specific antibodies
Disorders of exogenous toxins
• Sedative/hypnotic drugs and anesthetics ($GABA_A$ receptor enhancers) • Endogenous benzodiazepines • Ethanol intoxication and ethanol withdrawal • Ketamine, phencyclidine (NMDA receptor antagonist drugs) • Antidepressants • Neuroleptics • Opioids • Intoxication with antipyretic/analgesic medications • Intoxication with drugs of abuse • Intoxication with drugs causing metabolic acidosis

Abbreviations: CSF, cerebrospinal fluid; GABAA, γ-aminobutyric acid type A; NMDA, *N*-methyl-D-aspartate.

TABLE 19.6 Criteria for Determination of Unresponsive Wakefulness State (Also Known as *Vegetative State*)

1. No evidence of awareness of self or surroundings. Reflex or spontaneous eye opening may occur.
2. No meaningful and consistent communication between examiner and patient, auditory or written. Target stimuli not usually followed visually but sometimes visual tracking present; no emotional response to verbal stimuli
3. No comprehensible speech or mouthing of words
4. Smiling, frowning, or crying inconsistently related to any apparent stimulus
5. Sleep-wake cycles present
6. Brainstem and spinal reflexes variable, eg, preservation of sucking, rooting, chewing, swallowing, pupillary reactivity to light, oculocephalic responses, and grasp or tendon reflexes
7. No voluntary movements or behavior, no matter how rudimentary; no motor activity suggesting learned behavior; no mimicry. Withdrawal or posturing can occur with noxious stimuli.
8. Usually intact BP control and cardiorespiratory function; incontinence of bladder and bowel

Abbreviation: BP, blood pressure.

intact cardiorespiratory function, and primitive responses to stimuli but without evidence of inner or outer awareness present for at least 1 month (Table 19.6). In contrast, patients with MCS intermittently show signs of low-level awareness with or without intact language function. These may include eye tracking and visual smooth pursuit for the former and inconsistent command following for the latter. Identifying this state is important because it may represent a transitory state on the road to recovery.

Likewise, both in the chronic as well as acute disorders of consciousness context task-based EEG or functional MRI allows detection of volitional brain activation in behaviorally unresponsive patients. This brain activation may include only the primary or association cortices suggesting different levels of complexity in the brain response. Detection of this state, called *cognitive motor dissociation*, early after brain injury is associated with later behavioral recovery and functional outcomes.

Predicting recovery of consciousness and long-term functional outcomes is challenging early after the injury, as outlined above. Electrophysiologic and imaging assessments of the brain at rest (ie, resting state MRI or EEG, positron emission tomography) and in response to sensory stimulation (ie, local global paradigms a type of late evoked potentials) are emerging as potential additions to the clinical examination. Particularly promising are motor command responses detected by functional MRI or EEG.

Patients who survive coma usually show varying degrees of recovery within 2 to 4 weeks; those who enter UWS may recover further, even fully. Increasingly, data indicate that much of our formerly pessimistic assumptions regarding outcome of comatose patients are likely based on self-fulfilling prophecies and biases. Approximately three of four unconscious patients with acute brain injury die from withdrawal of care. This is concerning because our ability to accurately predict long-term outcomes in these patients is extremely poor. In the Multi-Society Task Force study, patients remaining in the UWS 3 months after traumatic brain injury were associated with a 35% rate of recovery of consciousness at 1 year, and 16% of these patients recovered independent function by 1 year after injury. The majority (>80%) of patients remaining in MCS at 3 to 6 months after injury will improve, some eventually demonstrating no disability. Patients with traumatic brain injury tend to have better recovery compared to those with anoxic-ischemic injury. Much research is currently directed toward identifying predictors of who will recover to which state at what time. Amantadine hydrochloride 100 mg 3 times a day has been shown to accelerate the pace of functional recovery among patients with UWS and MCS after severe traumatic brain injury LEVEL 1.[1] Also under study are the use of the pharmacologic interventions (eg, zolpidem) and thalamic stimulation.

BRAIN DEATH

Unlike the disorders of consciousness discussed above including the UWS/VS in which the brainstem and possibly other areas of the brain are intact, the term *brain death* refers to a state in which the cerebrum and the brainstem are both permanently destroyed. The only spontaneous activity is cardiovascular; apnea persists in the presence of hypercarbia sufficient for respiratory drive, and the only reflexes present are those mediated by the spinal cord. In adults, brain death rarely lasts more than a few days and is always followed by circulatory collapse despite persistence on a ventilator. In the United States, brain death is equated with legal death. When criteria are met, artificial ventilation and blood pressure support are appropriately discontinued, regardless of whether or not organ harvesting is intended. Detailed information on how to diagnose and manage brain death in the ICU is provided in Chapter 20.

FUTURE DIRECTIONS

Functional imaging and EEG provides biomarkers to study interventions to support the recovery of consciousness. Likely, these will need to be targeted based on individual phenotypes of the underlying brain injury.

Brain Death 20

Eelco F. M. Wijdicks

KEY POINTS

1. Brain death determination is a clinical assessment.
2. A number of preconditions are required.
3. Apnea test is a safe procedure when guidelines are followed.
4. Brain death often results in organ donation.

INTRODUCTION

Brain death is used to describe an apneic patient with not only irreversible coma from a massive brain injury but also loss of all brainstem reflexes and often uncontrolled diuresis and hypotension from loss of vascular tone. Nothing else should explain this condition, and characteristically, it is due to an acute catastrophic bihemispheric and diencephalic injury that has progressed to total brainstem injury. Brain death remains uncommon because such progression would require not only involvement of both hemispheres of the brain but also loss of brainstem function. Typically, this clinical situation would be an acute massive hemispheric lesion (eg, cerebral hemorrhage) compressing and sequentially damaging the mesencephalon, pons, and medulla oblongata (Fig. 20.1). The brainstem is very resilient to injury, and it would take a substantial shift (from mass effect) or poor perfusion (from basilar artery occlusion or massively increased intracranial pressure) for it to get permanently damaged. This core neurologic principle—the brainstem to be the last brain structure to go out of function—is the most important attribute to our understanding of brain death. Once brainstem function is lost, breathing stops first and the heart soon thereafter. If in the acute phase the patient can be intubated, placed on a mechanical ventilator, sufficiently oxygenated, fluid resuscitated, and vasopressors and vasopressin added, this agonal sequence can potentially be halted for some time.

Once an untreatable catastrophic neurologic structural injury has been proven and the brainstem reflexes have disappeared, recovery does not occur, and there is no known effective medical or surgical intervention. The clinical diagnosis involves testing of absent motor responses, loss of all brainstem reflexes, and observation of apnea after a carbon dioxide challenge in a patient temporarily detached from the ventilator. Irreversibility is not determined by observation over time but determined by these findings.

Brain death determination requires a skill set but is relatively straightforward. Physicians should work through a set of criteria and not be swayed by supposedly quicker options.

FIGURE 20.1 Supratentorial lesions (mass, cerebral edema) leading to rostrocaudal damage of the brainstem and eventually to brain death. *Arrows* point at direction of tissue compression and loss of function. (Courtesy of the Mayo Foundation for Medical Education and Research.)

The fundamental medical principle is that brain death is death, and organ and tissue donation must be a priority. This chapter provides ways on how to proceed with this evaluation and how to prevent common pitfalls.

THE CLINICAL DIAGNOSIS OF BRAIN DEATH

Declaring a patient brain dead can be considered in a comatose patient with a major destructive brain injury, loss of at least three brainstem reflexes, and no evidence of a breathing effort. A more formal assessment, however, may only proceed when the patient worsens even more, when all medical or neurosurgical interventions are futile, and when there are no confounding factors or alternative explanations. The clinical examination starts when a patient with a massive acute brain injury has no motor response to pain, fails to grimace to pain, has absent brainstem reflexes, and does not trigger the ventilator. Commonly, the patient has become hypotensive and polyuric from diabetes insipidus and has been placed on vasopressors. Using this starting point, many patients will fulfill the criteria of brain death after detailed neurologic examination. With any other (earlier) starting point, there is a greater chance that there will be retained brainstem function and even spontaneous breathing when the patient is briefly disconnected.

Determine the Cause of Brain Death

Brain death evaluation involves several sequential steps (Table 20.1). First, there is nothing more important than to be very certain that all possible confounding factors have been excluded. This implies there can be no lingering effects of prior sedation, other confounding medications, or prior use of illegal drugs or alcohol. A reasonable guideline is to calculate 5 to 7 times the drug's elimination half-life in hours and allow that time to pass before clinical examination is performed. Examples of long elimination half-life drugs are phenobarbital (100 h), diazepam (40 h), amitriptyline (24 h), primidone (20 h), and lorazepam (15 h). A commonly used short-acting benzodiazepine is midazolam, but the elimination may still take 3 hours. Prior use of therapeutic hypothermia may substantially slow down the metabolism of medications such as lorazepam and fentanyl used to support the procedure. Substantial alcohol levels should be excluded, but alcohol content below the legal alcohol limit for driving (blood alcohol content 0.08%) is acceptable to determine brain death. Absence of neuromuscular blockade (defined by the presence of four twitches with a train of four with maximal ulnar nerve stimulation) should be demonstrated but is likely if the patient has tendon reflexes (or breathes). Furthermore, absence of severe electrolyte, acid-base, or endocrine disturbances (defined by marked acidosis or any substantial deviation from the normal values) should be documented. A core temperature greater than 32°C must be present, but preferably, there should be near normothermia (36°C-37°C), which can be achieved with a warming blanket—assuming the patient is not a victim of environmental severe hypothermia. Systolic blood pressure should be greater than 90 mm Hg because pupil size and light reflex can fully disappear with lower values. Only after these confounders have been addressed should a more formal examination proceed.

TABLE 20.1 Checklist for Establishing Brain Death

Prerequisites (ALL MUST BE CHECKED)
☐ Coma, irreversible and cause known
☐ Neuroimaging explains coma
☐ Sedative drug effect absent *(if indicated, order a toxicology screen)*
☐ No residual effect of paralytic drug *(if indicated, use peripheral nerve stimulator)*
☐ Absence of severe acid-base, electrolyte, or endocrine abnormality
☐ Normal or near normal temperature *(core temperature ≥36°C)*
☐ Systolic blood pressure ≥100 mm Hg
☐ No spontaneous respirations
Examination (ALL MUST BE CHECKED)
☐ Pupils non-reactive to bright light *(typically mid-position at 5-7 mm)*
☐ Corneal reflexes absent *(use both saline jet and tissue touch)*
☐ Eyes immobile, oculocephalic reflexes absent *(tested only if C-spine integrity ensured)*
☐ Oculovestibular reflexes absent *(50 cc of ice water in each ear sequentially)*
☐ No facial movement to noxious stimuli at supraorbital nerve or temporomandibular joint compression *(absent snout and rooting reflexes in neonates)*
☐ Gag reflex absent *(gloved index finger to posterior pharynx)*
☐ Cough reflex absent to tracheal suctioning *(at least 2 passes)*
☐ No motor response to noxious stimuli in all 4 limbs *(triple flexion response is most common spinal-mediated reflex)*
Apnea Testing (ALL MUST BE CHECKED)
☐ Patient is hemodynamically stable *(systolic blood pressure ≥ 100 mm Hg)*
☐ Ventilator adjusted to normocapnia *($PaCO_2$ 35-45 mm Hg)*
☐ Patient pre-oxygenated with 100% oxygen for 10 minutes *(PaO_2 ≥ 200 mm Hg)*
☐ Patient maintains oxygenation with a PEEP of 5 cm H_2O *(if not, consider recruitment maneuver)*
☐ Disconnect ventilator
☐ Provide oxygen via an insufflation catheter to the level of the carina at 6 liters/min or attach T-piece with CPAP valve @ 10-20 cm H_2O and resuscitation bag
☐ Spontaneous respirations absent
☐ Arterial blood gas drawn at 8-10 minutes, patient reconnected to ventilator
☐ $PaCO_2$ ≥ 60 mm Hg, or 20 mm Hg rise from normal baseline value or Apnea test aborted and confirmatory ancillary test *(EEG or cerebral blood flow study)*
Documentation
• Time of death *(use time of final blood gas result or use time of completion of ancillary test)*

Imaging Confirmation of Brain Death

Next, the computed tomography (CT) scan should be carefully reviewed and expectedly demonstrate massive brain destruction. Abnormalities may include a large mass with brain tissue shift, multiple hemorrhagic lesions, or diffuse cerebral edema with obliteration of basal cisterns. The CT scan can be initially normal

if the patient has been imaged very early after cardiopulmonary arrest. However, in the patients with anoxic-ischemic encephalopathy who eventually fulfill these criteria, brain edema or marked hypodensities in thalami, caudate nuclei, and basal ganglia are typically seen on a repeat CT scan. A normal CT should under no circumstances be acceptable. In some cases of cardiac arrest, a magnetic resonance imaging can be helpful to demonstrate the full extent of ischemic tissue damage compatible with brain death.

Clinical Examination

The main components of neurologic examination and technique of the apnea test in a patient suspected of brain death are summarized in **Table 20.1**.

Cranial Nerves

Clinical examination can proceed after these aforementioned hurdles have been cleared. The examination begins with evaluation of pupillary responses. Pupils should be midposition (4-6 mm) and unresponsive to light. A magnifying glass or handheld pupillometer can be helpful, in particular, when there is an uncertainty about the reactivity of pupils. One should be aware that atropine used during cardiopulmonary resuscitation may cause pupillary dilation, but intravenous drugs do not change reactivity. The corneal reflex is tested with squirting water on the cornea or by touching with a tissue and no blink response should be seen. (Subtle blink responses may be only a movement of eyelashes.) Oculocephalic reflexes ("doll's eyes") should be absent bilaterally (fast turning of the head to both sides should not produce any ocular movement). The oculovestibular response ("cold calorics") should be absent. The head should be elevated 30°. Approximately 50 mL of ice water is then infused in the external auditory canal. No eye movement should be observed for 2 minutes. The examination then proceeds with evaluation of gag and cough reflexes, both of which should be absent. Gag reflex could be tested by a movement of the endotracheal tube but is far more reliable with sticking a gloved finger of the examiner deep in the back of the throat moving the uvula. Cough reflex should be tested by deep bronchial suctioning and with at least two passes.

Motor Responses to Pain

The comatose patient should be unresponsive to verbal or painful stimuli. Standard noxious stimuli include compression of the supraorbital nerves, forceful nail bed pressure, and bilateral temporomandibular joint compression. Eye opening to noxious stimuli should be absent. No motor response should be observed. Some motor responses may be preserved, and the challenge is to label them as "spinal responses." They may occur with neck flexion and nail bed compression but are absent with supraorbital nerve compression. These responses are not classifiable as decorticate or extensor responses because that would imply an intact subcortical circuitry. These responses are uncommon—and far less common than claimed in the literature—but include triple flexion responses, finger flexion or extension, head turning, and slow arm lifting. These movements do, on occasion, cause concern for the family members (and later even transplant surgeons) and have to be properly explained and documented in the medical record.

Apnea Testing

Finally, absent breathing is proven with a formal apnea test. The apnea test is best performed under controlled circumstances and with disconnection of the mechanical ventilator. The ventilator may spuriously indicate a breathing drive of the patient, and this phenomenon—caused by minimal pressure or volume changes in the breathing circuit—is quite commonly not recognized. There is a real concern that some patients with "retained breathing drive" may have been excluded from formal testing, or worse, a prolonged waiting time for the respiratory drive to "disappear" may have led to premature cardiac arrest in a potential organ donor.

The apnea test is a complex testing procedure. The apnea test cannot proceed if preconditions are not met and the patient is not prepared (preoxygenation, reducing positive end-expiratory pressure to 5 cm of H_2O and drawing a baseline blood gas). Once ready, the patient is disconnected from the ventilator while an oxygen source is provided with an oxygen flow catheter placed at the level of the carina. The oxygenation diffusion method is very safe method with few aborted tests and in our experience less than 2 %. Demonstration of apnea with a rise in P_{CO_2} to 60 mm Hg or 20 mm Hg about a normal baseline value after completion of the brainstem reflexes defines brain death and death of the patient (the time of the second blood gas is best used as the official time of death).

Ancillary Tests to Confirm the Diagnosis of Brain Death

Technical tests to support the clinical diagnosis of brain death have been developed and may demonstrate absent blood flow to the brain or absent electrical activity of the cortex (**Table 20.2**). These tests have considerable inaccuracy and should not replace, in any way, a clinical assessment. Interpretation of these tests, when results are not obvious, remains difficult, and results of multiple tests may not be matching. Elevating an ancillary test to a diagnostic test may lead to errors in brain death determination. Ancillary tests are used in less than 5% of patients diagnosed with brain death and are better generally avoided. These tests have mostly been used when there is an inability to perform an apnea test (due to poor oxygenation of the patient, hemodynamic instability, or evidence of prior chronic carbon dioxide retention). Some countries in the world legally require performing these tests, but in the United States, there is no such requirement. Once the patient is declared brain dead and time of death is documented in the medical record, decisions can be

TABLE 20.2 Tests Commonly Used for the Confirmation of Brain Death

1. **Electroencephalography (EEG):** Confirmation of neocortical death can be documented by at least 30 min of electrocerebral silence using a 16-channel instrument with increased gain settings, according to guidelines developed by the American Electroencephalographic Society. If any brain wave is present, the diagnosis of brain death cannot be made. The EEG confirmation of brain death is also not valid in patients exposed to sedatives or toxins because they can directly suppress the brain electrical activity.
2. **Digital subtraction or CT angiography:** Complete absence of intracranial blood flow above the level of the proximal internal carotid and vertebral arteries confirms the diagnosis of brain death.
3. **Radioisotope cerebral imaging:** The complete absence of cerebral perfusion can also be established using radionuclide angiography or single-photon emission computed tomography (SPECT).
4. **Transcranial Doppler ultrasonography:** A velocity profile showing systolic spikes with absent or reversed diastolic flow is consistent with the cessation of cerebral blood flow and brain death.

Abbreviation: CT, computed tomography.

made without further hesitation and should first involve notification of organ donation agencies. Refusal of organ donation (in estimated 30% of cases) will lead to withdrawal of support.

BRAIN DEATH IN CHILDREN

Brain death in children was recently revisited by a multidisciplinary task force. Most concerns regarding interpretation of neurologic examination are in neonates several months old, and the advanced skills of a neonatologist are needed to obtain reliable findings. Examination of a child in an incubator remains limited, and neurologists should be aware of incompletely developed brain function and motor response. The new pediatric guideline suggests a 24-hour interval between examinations by two physicians in neonates and children from 37-week gestation to the end of the first month. However, in children aged 1 month or older, the pediatric guidelines still impose two examinations 12 hours apart by two different attending physicians. Two examinations in children are different from adults, but the need for such a distinction is highly questionable. The guideline also recommends that physicians be competent to perform examinations in infants and neonates but speculatively suggest that these examinations be performed by pediatric intensivists and neonatologists, pediatric neurologists and neurosurgeons, pediatric trauma surgeons, and pediatric anesthesiologists with critical care training.

COMMON DIAGNOSTIC CHALLENGES AND PITFALLS

The examination and later communication with distraught family members require experience. There are situations that can easily create unease and uncertainty. Some common mistakes are shown in **Table 20.3**. Most pitfalls relate to premature assessment of the patient and suggesting the patient might be brain dead when there has not been a formal evaluation.

Targeted temperature management has become a common treatment of comatose patients following cardiopulmonary resuscitation. However, the category of patients who fulfill brain death after cardiopulmonary resuscitation more often are hemodynamically unstable, and many of them die from irreversible cardiac shock before brain death can be determined. The clinical examination of brain death may be difficult to complete due to persistent hypotension and use of multiple vasopressors. The apnea test may also be compromised due to the presence of significant pulmonary edema from cardiac failure. How to assess these patients after prior use of therapeutic hypothermia and use of sedative drugs and recovering from shock liver or acute renal failure remains unclear, and it may be prudent not to proceed with a brain death examination at all. Targeted temperature management in a patient with an infusion of fentanyl or midazolam—certainly both—will seriously confound neurologic examination. There is no precise way to calibrate the effect of confounders, particularly because metabolic effects persist after rewarming, especially for drugs with long half-lives.

The most important challenge for physicians is to perform a complete examination in patients with primary lesion in the brainstem. More often than not, physicians will find patients with a primary brainstem lesion or a compressed brainstem from a cerebellar lesion that do not fulfill all criteria of brain death and may even benefit from aggressive intervention (ventriculostomy or suboccipital craniotomy). A destructive primary brainstem lesion is as irreversible lesion as the one that involves the hemispheres and brainstem, and it is therefore unnecessary to perform an ancillary test. These tests often will show preserved blood flow when the intracranial pressure has not increased to extreme values, and early electroencephalography may show nonreactive alpha or spindle coma patterns.

Ancillary testing demonstrating complete intracranial circulatory arrest by catheter or CT angiography or a radionuclide brain perfusion study remains very problematic if used to confirm brain death in the setting of confounding medications, hypothermia, or metabolic disarray.

TABLE 20.3 Common Misjudgments in the Diagnosis of Brain Death

• Incomplete testing
• Examination in a patient with confounders (mostly recently administered medication, drug, and alcohol use)
• Use of cerebral blood flow study as a diagnostic test
• Misinterpretation of ancillary test
• Misinterpretation of "spinal reflexes"
• Premature discussion with family about brain death and organ donation

INTENSIVE CARE UNIT MANAGEMENT OF THE POTENTIAL ORGAN DONOR

Brain death eventually leads to severe homeostatic derangements and cardiac arrest despite mechanical ventilation and aggressive life support measures. This inexorable progression toward multisystem organ failure creates a challenge in managing the potential organ donor, in whom the goal is to maintain and optimize organ viability for transplantation. However, in some patients, acute neurogenic pulmonary edema and stress cardiomyopathy can subside in 24 to 48 hours and provides the opportunity for organ donation.

Most patients become hypotensive due to sudden loss of resting sympathetic tone and require intravenous pressors at the time brain death occurs, and soon thereafter, they develop diabetes insipidus (because antidiuretic hormone secretion ceases). *Arginine vasopressin* is the first-line therapy for hypotension in brain death because it works effectively and also because it guards against central diabetes insipidus, which also occurs in the majority of brain dead patients. Adrenergic vasopressors such as norepinephrine or dopamine can also be added, but their usefulness can be limited by tachyarrhythmias, severe peripheral vasoconstriction, or aggravation of sympathetically mediated myocardial injury. In some cases, continued hypotension will respond to thyroid and glucocorticoid hormone replacement, indicating a relative deficiency of these hormones. Management of the organ donor in the United States is fully directed by the organ donation agency.

ETHICAL ISSUES

Some physicians and ethicists have repudiated the infallibility of terminal cardiac arrest, questioning irreversibility and even the definition of death. With improving intensive care unit technology and, certainly, with the introduction of multiple vasopressors, terminal cardiac arrest—albeit expected—may not occur quickly anymore. Isolated reports of prolonged somatic support of brain-death patients may have religious, cultural, legal, and pecuniary motives but remain conspicuously unexamined at these later stages, and it is likely many, if not most, did not fulfill the 2010 American Academy of Neurology criteria. Prolonged care followed by cesarean section has been provided in rare circumstances such in brain death in advanced pregnancy. Providing support until delivery is rarely successful if the brain death mother has no viable fetus. More recently, neurologists have been confronted with families intervening with neurologic testing, which includes an apnea test. When families deny brain death as a definition of death, legal counsel is required.

CONCLUSIONS

Brain death examination requires expertise and follows a stepwise protocol. It is an obvious enough fact that the diagnosis of brain death is complex due to its clinical testing, in determination of confounding factors, and in the interpretation of ancillary tests. The responsibilities of neurologists are substantial also because it eventually involves organ transplantation.

Computed Tomography 21

Priya Shoor, Daniel S. Chow, and Angela Lignelli

KEY POINTS

1. Noncontrast head computed tomography (CT) is the most appropriate first-line imaging in the evaluation of a patient with unexplained acute neurologic deficit suggesting a brain or brainstem localization.
2. CT head can rapidly identify processes demonstrating intracranial mass effect, midline shift, and increased intracranial pressure.
3. Low-osmolar contrast enhanced CT is useful for the evaluation of pathology that involves the breakdown of the blood-brain barrier such as primary tumor, metastatic lesions, infections, and inflammatory conditions.
4. Identification of subarachnoid hemorrhage on a noncontrast head CT warrants further evaluation with vessel imaging including CT angiography, magnetic resonance angiography, and/or conventional angiography.
5. In acute stroke, CT angiography should be performed as a first-line test in addition to noncontrast head CT in order to diagnose large vessel occlusion (LVO), which can be treated with thrombectomy.
6. CT perfusion provides quantitative color maps of cerebral blood volume and flow, cerebral mean transit time, and time to peak and may be used to quickly differentiate ischemic core from penumbra and identify candidates for thrombectomy in the 6-24 hour time window.

INTRODUCTION

This chapter provides a framework for understanding the basic principles of x-ray (roentgenogram) production and computed tomography (CT) image formation along with appropriate window and level parameters for evaluation of intracranial pathologies. In addition, the common indications for CT are discussed along with precautions and recommendations related to CT usage and iodinated contrast. Advanced CT modalities including CT perfusion and CT angiogram are given special consideration.

Description

CT is based on image reconstruction from sets of quantitative x-ray measurements through the head. A beam of x-rays serves as the source of photon energy, which is received by a detector. Although the exact physics of x-ray production is beyond the scope of this chapter, this section tries to simplify the basic principles of x-ray production important for image formation. Briefly, x-ray beams are generated when electrons, produced in the cathode of the tube unit, strike the anode target. The potential difference across the tube is measured as peak kilovoltage. Thus, increasing the peak kilovoltage increases the energy of x-rays produced, which will increase penetration of the beam during image production but decrease contrast (and vice versa). Imaging intravenous (IV) or oral contrast in CT imaging is based on the differential attenuation of the x-ray beam through various tissues. As the electron density of the tissue increases, the attenuation increases (giving a "whiter" image). Therefore, the bony calvarium appears "white" compared to soft tissue and air because of its greater attenuation.

Modern CT scanners use highly collimated x-ray beams, which are rotated over many different angles to obtain a differential absorption pattern across various rays through a slice of a patient's body. A circular scanner gantry houses the x-ray source and detectors; the plane of the circle can be tilted to perform scans at a range of angles from axial to coronal, depending on head position and scanner specifications. The x-ray source rotates around the patient's head, and the x-ray attenuation through the section plane is measured in compartments called *voxels*. A voxel is a volume element similar to a picture element, or pixel, with the added dimension of section thickness to create an image volume component. Through projection reconstruction, the computer creates or builds the image from more than 800,000 measurements per image plane and assigns a number to each voxel according to its x-ray attenuation (which is proportional to tissue electron density averaged over the volume of the voxel). These values are termed *Hounsfield units* (**Table 21.1**) in honor of Nobel Prize winner Sir Godfrey Hounsfield who first developed CT technology in 1973.

CT of the head differentiates cerebrospinal fluid and brain as well as white matter and cortical gray matter, delineates the

TABLE 21.1 Hounsfield Units for Common Structures

Structure	HU
Air (blackest)	−1,000
Fat	−100 to −50
Water	0
Cerebrospinal fluid	0-15
White matter	20-30
Gray matter	35-45
Acute hemorrhage[a]	45-65
Bone (whitest)	>500

[a]In patients with anemia or iron deficiency, Hounsfield unit (HU) values for hemorrhage may be lower.

FIGURE 21.1 Noncontrast computed tomography of the head with standard brain **(A)** and narrow stroke **(B)** windows in a patient with acute right-sided weakness. Stroke windows reveal loss at the left insular ribbon *(arrows)*, which was not clearly visualized on conventional windows.

deep gray nuclei from the internal capsule, and images the skull and skull base in detail. Noncontrast computed tomography (NCCT) of the brain is especially useful for identifying acute hemorrhage, which is easily and reliably visualized as higher density than normal brain or cerebrospinal fluid. Typically, intracranial arteries are not well delineated on standard NCCT. Iodinated water-soluble contrast agents, which have high x-ray density, when administered intravenously enhance differences in tissue density, demonstrate vasculature and vascular pathology, and detect areas of blood-brain barrier breakdown.

A major limitation of CT has been imaging the posterior fossa, where linear artifacts appear because bone selectively attenuates the low-energy components of the x-ray beam; the resulting "beam hardening" creates dense or lucent streaks that project across the brainstem and may obscure underlying lesions in the brainstem and cerebellum. However, new detector technology and image-processing algorithms have reduced this artifact in the latest CT scanners, improved spatial resolution, and reduced the radiation dose. Current CT technology allows scan time per section ("slice") to be shortened to less than 1 second to minimize motion artifact. Multisection helical CT can acquire contiguous thin sections to produce three-dimensional (3D) data sets of an entire body part, such as the neck or head. Rapidly, repeated acquisitions can be used to acquire dynamic computed tomography angiography (CTA) and computed tomography perfusion (CTP) studies, which is discussed later in this chapter.

Windows and Levels

Although CT imaging can display 4,096 shades of gray, the human eye can only visualize between 16 and 32 shades of gray, which is well beyond human perception. "Windowing" allows users to narrow the range of shades of gray, which in turn adjusts the contrast scale. Two factors that can be adjusted by the user are the window width (W) and the window level (L). The W determines the range of shades of gray that can be displayed. Therefore, "narrowing the window" would increase the contrast of the image. The L determines the center of the W. By convention, users can decrease the W by dragging the mouse from right to left, increasing the contrast. The L can be decreased by dragging the mouse from top to down on monitors.

Although the default "brain window" (80 W 40 L) is suitable for assessing a wide range of pathologies, there are several other important windows for neuroimaging to assess for subtle abnormalities. For example, evaluation of parenchymal hypodensity as a marker for early infarct in stroke patients may be improved by using narrow windows (35 W 35 L) (**Fig. 21.1**). Additionally, subdural hemorrhages are often located at the convexities adjacent to bone and may be difficult to identify due to beam hardening and volume averaging. Using wider windows may assist in countering these limitations (**Fig. 21.2**). Lastly, bone windows (2,000 W 210 L) are

FIGURE 21.2 Noncontrast computed tomography of the head with standard brain **(A)** and wider subdural windows **(B)** in a patient after fall. Subdural windows reveal a subdural hematoma at the left parietal convexity *(arrows)*, which is not clearly visualized on conventional windows.

FIGURE 21.3 Noncontrast computed tomography of the head with standard brain **(A)** and bone **(B)** windows in a pediatric patient after fall. Bone windows reveal a nondisplaced hairline fracture of the right temporal bone, which is not visualized on conventional brain windows.

formed with wide ranges and centered above soft tissues and are best for evaluating for subtle nondisplaced calvarial fractures (Fig. 21.3).

ROLE OF COMPUTED TOMOGRAPHY

For reasons of cost, speed, and availability, CT remains widely used for screening in the acute evaluation of trauma, stroke, and infections (Table 21.2). CT is widely accepted as the more reliable method for detection of acute brain parenchymal or extra-axial hemorrhage, especially subarachnoid hemorrhage. It is particularly useful for patients who are neurologically or medically unstable, uncooperative, or claustrophobic as well as for patients with pacemakers or other metallic implants that may be contraindications for magnetic resonance imaging (MRI). The principle drawback of CT is its use of ionizing radiation, which is discussed at the end of this chapter. Although there are numerous indications for obtaining a CT examination of the central nervous system, this section briefly focuses on the appropriate use of CT in common clinical scenarios.

Head Trauma

An NCCT is the most appropriate first study for evaluation of acute head trauma. In patients with moderate or high risk for intracranial injury, there is consensus that postinjury NCCT is useful in excluding intracerebral hematoma, midline shift, or increased intracranial pressure. Additionally, NCCT is also very sensitive for identification of acute trauma in patients with minor head injury with the following risk factors: headache, vomiting, drug/alcohol intoxication, age older than 60 years, short-term memory deficit, physical findings of supraclavicular trauma, and/or seizure. CT's advantage for evaluation of traumatic injury includes its sensitivity for acute hemorrhage, fractures, and mass effect. CT is limited by its relative insensitivity to lesions adjacent to bony surfaces (ie, at the greater sphenoid wing) due to streak artifact. Additionally, diffuse axonal injury may go undetected.

TABLE 21.2 Common Indications for Emergency Computed Tomography Examination

Acute or chronic focal neurologic deficit
Head or facial trauma
Headache
Change in mental status
New-onset seizure

Headache

Routine screening head CT is generally not warranted in patients with chronic headaches in the absence of focal neurologic symptoms, change in headache pattern, or history of seizure activity. Several studies have confirmed the low yield of neuroimaging in individuals with isolated headaches and have reported a 0.4% yield for treatable lesions. However, neuroimaging is likely to be of greater yield for particular patient populations. For example, patients with cancer, immunocompromised status, or other systemic illness are more likely to have a "positive" scan. Imaging may also offer greater yield in headaches associated with trauma, abrupt or worsening headache, headache radiating to the neck or suspected meningitis, positional headache, or temporal headaches in older patients. Regarding suspected meningitis, CT imaging is often performed prior to lumbar puncture to assess for elevated intracranial pressure.

Subarachnoid Hemorrhage

NCCT imaging remains the most appropriate choice of imaging for patients with suspected subarachnoid hemorrhage, and failure of obtaining a head CT accounts for 73% of misdiagnosis. Patients diagnosed with subarachnoid hemorrhage require imaging of the cerebral vasculature, which may include CTA, magnetic resonance angiography, or direct catheter angiography. CTA has gained popularity and is frequently used for its noninvasiveness and sensitivity and specificity comparable to that of cerebral angiography.

Stroke

Initial workup for patients with suspected acute stroke is an NCCT in patients who are candidates for IV tissue plasminogen activator in order to differentiate between hemorrhagic and ischemic infarcts. NCCT remains the standard of care imaging

modality for exclusion of intracranial hemorrhage. In considering patients for endovascular therapies, the American Society of Neuroradiology, American College of Radiology, and Society of NeuroInterventional Surgery have recommended that appropriate imaging options include NCCT followed by digital subtraction angiography, or NCCT with CTA and perfusion CT, or MRI (with perfusion) and magnetic resonance angiography. Although NCCT has relatively low sensitivity to early ischemic injury compared to magnetic resonance diffusion imaging, it is not recommended that these findings be used to withhold IV tissue plasminogen activator treatment. With regard to CTP and CTA, its use has gained increased popularity in acute stroke evaluation and is discussed in the subsequent section.

COMPUTED TOMOGRAPHY PERFUSION AND ANGIOGRAPHY

Spiral CT increases scanning speed and image acquisition to less than 1 second per section and allows large-volume acquisitions that can be used for 3D presentation of anatomic information. Advances in CT technology have widened the extent of coverage per scan rotation from 2 cm (32 slices) to 4 cm (64 slices) and most recently to 16 cm (320 slices), which allows a set of images of the entire head to be obtained in a few rotations as the patient moves through the scanner or in as little as a single subsecond scan rotation in a stationary patient using the widest detector array. Rapidly repeating the scan acquisitions at 2 or 3 times per second during a bolus of IV contrast produces a set of "dynamic" images through a volume of tissue as wide as the detector array. This approach, with the widest detector array on a cone beam computed tomography, can be used to produce whole-brain "real-time" four-dimensional images of blood flow through the intracranial vessels (CTA) combined with "functional" images of brain parenchymal blood flow (CTP) in a total time of 1 minute, with a single IV contrast bolus injection.

CTA allows vascular imaging with IV contrast agents. Without contrast, intracranial vessels are not well seen on CT, unless abnormally large or dense—as with a thrombus. As previously described, modern CT scanners allow for rapid imaging, which permits noninvasive arterial phase imaging. Advantages of CTA over catheter angiography include more widely available technology; less specialized skill requirements; and no risk of dissection, stroke, or pseudoaneurysm at groin site. A limitation of CTA is the time-consuming processing required to edit out bone and calcium and to generate 3D surface renderings, although this has improved with the availability of specialized software that partially automates this process. *Maximum intensity projection* reformations or 3D renderings with surface shading can be used to display vascular anatomy and abnormalities such as stenosis or aneurysm with either of these approaches.

CT perfusion allows quantitative measures of cerebral blood volume (CBV), cerebral mean transit time (MTT), time to peak, and cerebral blood flow (CBF). These parametric maps can be easily generated at a work station, following the IV bolus administration of contrast. Perfusion imaging measurements can be used as a quick screening method in assessment of acute cerebral ischemia in major vascular territories and for differentiating between infarct and penumbra, with results comparable to MRI perfusion. Specifically, the infarct core, that is, region of irreversible injury, has been described as prolonged MTT, decreased CBV, and decreased CBF. The ischemic penumbra, potentially salvageable tissue, is described as prolonged MTT and time to peak with normal or increased CBV and resultant mildly reduced CBF, thought to reflect compensatory vasodilatation. The combination of NCCT, CTA, and CTP allows CT imaging to provide a complete evaluation of acute stroke.

IODINATED CONTRAST ADMINISTRATION

Contrast-enhanced CT is used to detect lesions that involve breakdown of the blood–brain barrier, such as brain or spinal tumors, infections, and inflammatory conditions. Contrast-enhanced CT is often used to rule out cerebral metastases. However, it is less sensitive than gadolinium-enhanced MRI, which is also better for detection of primary intracranial tumors and infections. IV CT contrast agents are based on iodine, and the older agents are classified as high-osmolar contrast media. Newer, nonionic agents, classified as low-osmolar contrast media, are less allergenic, and they cause less morbidity than do high-osmolar contrast media. The majority of patients receiving IV iodinated contrast media will have suffer no ill effects. With use of low-osmolar contrast media, the overall incidence of reactions is between 0.2% and 0.7% with severe and life-threatening reactions occurring between 0.01% and 0.02%.

With regard to the risk factors, history of prior contrast reaction is associated with a 5 times greater likelihood of a subsequent contrast reaction. Other risk factors include history of anaphylaxis, atopy, asthma, and significant cardiac disease. Of note, history of shellfish allergy is no longer considered a risk factor for contrast administration. In patients at increased risk for allergic reaction, several premedication strategies have been proposed by the American College of Radiology (Table 21.3).

Another important consideration for iodine-based IV contrast agents is contrast-induced nephrotoxicity (CIN), which is defined as an acute deterioration in renal function following IV iodinated contrast administration in the absence of other nephrotoxic event. However, the majority of the prior literature studying the incidence of CIN has failed to include a control

TABLE 21.3 Premedication Strategies for Patients With Known Risk Factors to Intravenous Iodinated Contrast Agents[a]

Elective	Prednisone: 50 mg orally at 13 h, 7 h, and 1 h before contrast injection *or* Methylprednisolone: 32 mg orally 12 h and 2 h before contrast injection *plus* Diphenhydramine: 50 mg IV, IM, or orally 1 h before contrast
Emergent	In decreasing order of desirability: Methylprednisolone sodium succinate: 40 mg *or* Hydrocortisone sodium succinate: 200 mg IV every 4 h until contrast injection *plus* Diphenhydramine: 50 mg IV 1 h prior to contrast injection

Abbreviations: IM, intramuscular; IV, intravenous.

TABLE 21.4 Premedication Strategies for Patients at Risk for Contrast-Induced Nephropathy

1. A 3-mL/kg bolus 1 h prior to procedure followed by 1 mL/kg/h for 6 h postprocedure
2. N-acetylcysteine 600 mg orally or IV 12 h preprocedure, followed by 600 mg every 12 h orally or IV postprocedure × three doses

Abbreviation: IV, intravenous.

group. In one study with a control group by Newhouse et al involving 30,000 patients at a single institution, half of the control group (patients who did not receive contrast medium) displayed a change in serum creatinine of at least 25% and a change of 0.4 mg/dL in 40%. This study concluded that had some of these patients received IV iodinated contrast, a creatinine rise would have been attributed to it, rather than to physiologic variation. Nonetheless, it is important to recognize risk factors described for CIN, which includes preexisting renal insufficiency.

There is no universally agreed on threshold of serum creatinine elevation (or degree of renal dysfunction) to contraindicate intravascular iodinated contrast administration. With regard to prevention against CIN in patients receiving contrast, studies suggest that adequate hydration is beneficial. Although an accepted ideal infusion rate has yet to be established, isotonic fluids are preferred (ie, lactated Ringer or 0.9% normal saline). Protocols using sodium bicarbonate solution infusion or N-acetylcysteine exist for reducing the risk of CIN (Table 21.4). These are safe and reasonable therapeutic options when IV contrast is required for patients with chronic renal insufficiency, although their efficacy is not established.

Magnetic Resonance Imaging 22

Eric Newman and Angela Lignelli

KEY POINTS

1. Magnetic resonance imaging (MRI) is a high-resolution structural imaging modality with a broad application of clinical uses.
2. MRI is based on nuclear spin spectroscopy of water protons and does not involve ionizing radiation.
3. T1 sequences are useful in identifying structural neuroanatomy, contrast enhancement sequences, and acute hemorrhage.
4. T2-related sequences, including fluid-attenuated inversion recovery, are useful in a broad array of pathologic processes, especially evaluation of white matter diseases.
5. Diffusion-weighted imaging is especially helpful in acute ischemic stroke but may be abnormal in other metabolic, infectious, neoplastic, and neurodegenerative processes.
6. Susceptibility-weighted imaging identifies calcification or iron content and also has a broad array of clinical applications.
7. Vascular MRI, including angiography and venography, is most useful in the workup and localization of stroke.
8. Magnetic resonance spectroscopy is useful in differentiating some structural and metabolic changes, through identification of abnormal energy storage and anaerobic metabolism as well as cell membrane and myelin content.
9. Diffusion tensor imaging uses directional dependence of diffusion of water to assess the integrity of white matter tracts.
10. Functional MRI uses hemodynamic coupling of cerebral activation to indirectly infer cerebral activation and is primarily used for preoperative surgical planning and research.

INTRODUCTION

Magnetic resonance imaging (MRI) is a noninvasive medical imaging technique. The images created by MRI often appear similar to gross-anatomic specimens. The major strength of MRI is the ability to distinguish different soft tissues and identify pathologic abnormalities. It is indispensable to modern neurologic practice for diagnosis, confirmation, and characterization of neurologic conditions as well as for monitoring response to therapy. Although MRI signal abnormalities can be very sensitive to pathologic processes, in isolation, the findings may lack specificity, requiring thorough integration of clinical information. The main weaknesses of MRI are cost, inherent low signal to noise necessitating high magnetic fields as well as lengthy exam times, and distortion of images by artifacts. The MRI scanner consists of a bore that is generally small and constricting, creating anxiety or claustrophobia in many patients. In addition, implanted devices can be ferromagnetic and therefore contraindicated for MRI imaging, for example, some pacemakers. As in all radiologic procedures, contrast agents should be administered when the benefit of improved diagnostic accuracy outweighs their generally low risk. In the following paragraphs, the physics of MRI and technical considerations are discussed. In addition, the application of basic imaging sequences and advanced imaging methods are reviewed.

PHYSICS OF MAGNETIC RESONANCE IMAGING

MRI is based on Fourier transform nuclear spin spectroscopy of water protons. Clinical imaging is performed on the nuclear spin of water protons because water is abundant in biologic tissues and protons have relatively greater sensitivity in a magnetic resonance than other nuclei.

In the classical description relevant for clinical imaging, MRI can be understood by considering the spin properties of protons to be equivalent to small magnetic dipoles that align in a magnetic field. In the quantum mechanical description of proton magnetic resonance, individual proton spins exist as a combination (superposition) of two quantized energy states, transitions between which can be manipulated using radiofrequency pulses and delays. The very large number of water protons leads to behavior of biologic tissues in the magnetic field that can be thought of as net magnetization. This longitudinal magnetization can be *tipped* from the aligned state by a radiofrequency excitation pulse. The change in angle from the original aligned state is called the *flip angle*. Once in the transverse plane, the magnetization begins to rotate (precess) around the magnetic field at a specific resonant frequency called the *Larmor frequency* (~43 MHz per tesla for protons). This precessional motion in turn generates a time-varying voltage in a receiver coil. The specific resonance frequency depends on the nucleus being imaged, its local environment, and the magnetic field strength.

Relaxation of the signal back to equilibrium is described by the T1 and T2 exponential time constants. Relaxation of magnetization is not a spontaneous process but rather a phenomenon that is due to underlying molecular motion and molecular interactions. The BPP theory of relaxation named after Bloembergen, Purcell, and Pound has proven accurate and permits calculation of relaxation times from first principles. The two principal relaxation mechanisms are termed *T1* and *T2 processes*, which are relevant to clinical imaging and approximately depend on the

molecular tumbling rate or rather the rotational diffusion of individual molecules. The T1 time constant describes the recovery of longitudinal magnetization back to the equilibrium aligned state (after a time T1 ~63% of the magnetization has realigned). The T2 time constant describes the decay of magnetization in the transverse plane (after a time T2 ~63% of the magnetization has decayed).

Image Creation

MRI creates images by applying linear spatial magnetic field gradients so that different parts of the human body resonate at different frequencies. One dimension can be sampled directly (called the *frequency dimension*), whereas other dimensions can be sampled indirectly (called *phase dimensions*). By combining multiple gradient directions, two-dimensional or three-dimensional images can be constructed.

The MRI signal is composed of time-dependent damped sinusoids and requires Fourier transform to convert it to a power spectrum that is the image. The term *k-space* is used to refer to the time-dependent data. This is sometimes a source of confusion because the Fourier transform is very similar to its own inverse, and acquisition of time-dependent MRI data in k-space is essentially equivalent to acquisition of different frequency components of the image. For this reason, it is often noted that the center of the k-space image determines image contrast (low-frequency components), whereas the edges of the k-space image determine detail in the image (high-frequency components).

Since the first live human images were obtained in the late 1970s, the field has drastically expanded to include a wide variety of clinical applications. The sequence of radiofrequency pulses, gradient pulses, and intervening time delays used to prepare magnetization and the methods of sampling k-space are referred to as the *pulse sequence*. Different pulse sequences are also tailored for specific applications. The two basic sequences are gradient echo and spin echo techniques, upon which additional sequences can be derived. Gradient echo sequences refocus magnetization following a radiofrequency pulse using a field gradient, whereas spin echo sequences refocus magnetization using a radiofrequency inversion (180-degree) pulse. Spin echo sequences are generally less susceptible to artifacts because artifacts are also inverted by the refocusing pulse and subsequently cancel out.

CLINICAL MAGNETIC RESONANCE IMAGING SYSTEMS

Clinical imaging systems are rated by the strength of the main magnetic field, referred to the as the B_0 *field*, measured in tesla (1 T = 10,000 gauss ~15,000-40,000 the earth's magnetic field). The majority of clinical imaging systems use field strengths of 1.5 or 3 T. The term *high field* in the context of clinical imaging refers to magnet systems operating at 7 to 9 T. High-field systems have clear benefits in terms of improved anatomic resolution and increased signal to noise but are more prone to artifacts and require more radiofrequency power (higher specific absorption rate). Higher field magnets are typically closed-bore, meaning that they are shaped like long tube or cylinder. A variety of open-bore magnets is also commercially available. These magnets are more accommodating to variations in patient body habitus and typically create a less claustrophobic environment. Completely open-bore magnets operate at lower field strengths than closed-bore systems, with resultant lower resolution that may compromise clinical diagnosis.

Multiple components of the magnetic imaging system influence the ultimate sensitivity in detecting the magnetic resonance signal and generating a distortion-free image. One important physical factor that is changed between different applications is the radiofrequency coil. A variety of receive and transmit/receive coils are available for specific applications to the brain, head, neck, and spine. These include bird cage–type coils for imaging the brain, surface coils, multichannel, and parallel imaging coils, all of which have different trade-offs in terms of size of allowed imaging volume as well as sensitivity and speed of imaging.

MAGNETIC RESONANCE IMAGING SAFETY

The main safety considerations in MRI include the powerful main magnetic field, rapidly changing magnetic field gradients, deposition of radiofrequency power, sound pressure levels, and safety concerns related to contrast agents. The powerful magnetic field produced by an MRI scanner is a major safety consideration because objects can become dangerous projectiles when placed in the field. Moreover, non–MRI-compatible implanted devices or metallic foreign bodies pose a danger because of local tissue-heating effects and movement of the object in respect to critical structures. Commonly encountered devices in clinical practice include implanted cardiac devices (eg, cardiac pacemakers) as well as others such as infusion pumps, cochlear implants, and a variety of surgical implants such as some aneurysm clips. Recently, MRI-compatible cardiac devices have been devised and new MRI-compatible implanted surgical devices are being developed. However, precaution needs to be taken with every implanted device to ensure MRI compatibility and patient safety. Before the patient is even brought near the magnetic field, which is never turned off, a thorough safety check by appropriately trained medical personnel must be performed.

Once inside the MRI scanner, some patients may experience a variety of physical effects in addition to the possibility of claustrophobia. Federal limits on the main magnetic field strength imposed by the U.S. Food and Drug Administration are 8 T for adults and 4 T for neonates. Fields greater than these limits may pose a risk. Limits are also placed on the speed of the rapidly switching magnetic field gradients in MRI due to the possibility of neural or cardiac depolarization resulting in pain, auras, or possibly cardiac arrhythmias. Regulatory limits are also placed on the rate of energy deposition by radiofrequency pulses (eg, similar to limits placed on cell phones). This limit is referred to as the *specific absorption rate* and meant to prevent heating damage of body tissues.

Gadolinium chelates are commonly used contrast agents in MRI because of the local relaxivity effects that lead to T1 shortening and resultant bright signal on T1-weighted images. Other contrast agents including manganese-based contrast agents and superparamagnetic iron oxides are currently less common in clinical practice. The risk of contrast administration in the context of MRI includes contrast reactions that may be life-threatening. The deposition of gadolinium in tissues and resulting fibrosis, commonly known as *nephrogenic systemic fibrosis*, has been reported in patients with significantly reduced renal function necessitating appropriate screening.

BASIC SEQUENCES

For the purpose of clinical imaging, there are many sources of image contrast. Dynamic processes on the molecular level such as flow-related and diffusion effects and a variety of relaxation mechanisms are responsible for the power of MRI to generate contrast between different biologic tissues.

The basic sequences that are weighted for specific sources of image contrast are as follows:

- T1-weighted
- T2-weighted
- Fluid-attenuated inversion recovery (FLAIR) T2-weighted
- Diffusion-weighted
- Susceptibility-weighted
- Post–contrast-enhanced images

T1-Weighted and T2-Weighted Imaging

The two core sequences in magnetic resonance are T1-weighted and T2-weighted sequences, which individually emphasize either the T1 or the T2 relaxation time of tissues. *T1-weighted* imaging emphasizes *short T1* relaxation times as bright signal; tissues composed of spins with long T1 relaxation times will appear relatively lower signal intensity (dark) on T1-weighted images. The main clinical use of T1 imaging is to display brain and spinal cord anatomy. However, T1-weighted images are also useful to evaluate for subacute hemorrhage, lipids, paramagnetic metals, or proteinaceous composition of lesions, which all shorten the T1 relaxation time and appear bright on T1-weighted images. T1-weighted images also serve as the baseline comparison to contrast-enhanced images. T1-weighting can be accomplished by either decreasing the *repetition time* (TR) between successive excitations thus preventing magnetization from fully relaxing to equilibrium or by changing phase of successive radiofrequency pulses thus causing destructive inference (referred to as *spoiled gradient echo*).

The main clinical use of T2 imaging is to display brain and spinal cord pathology, as evidenced by increased tissue water content. *T2-weighted* images emphasize *long T2* relaxation times as a bright signal. Tissues composed of spins with short T2 relaxation times will appear dark on T2-weighted images. However, susceptibility effects resulting in local field inhomogeneities also decrease the T2 time (this type of effect is sometimes referred to as *T2**). T2 weighting can be accomplished by increasing the time the magnetization spends in the transverse plane, or *time to echo* (TE), prior to acquisition. Different from both T1-weighted and T2-weighted images, proton-density weighted images are obtained with a short TE to minimize relaxation losses and long repetition time to allow more magnetization to recover between successive excitations.

FLAIR is the preferred sequence for demonstrating subtle brain pathology. FLAIR images are obtained by preparing magnetization with a radiofrequency inversion pulse, which inverts the equilibrium alignment. As the magnetization relaxes back to the aligned state with the T1 time constant, it temporarily becomes negligible as it crosses zero and timing detection at this time can essentially null signal from spins with a specific T1. Although FLAIR sequences can be T1- or T2-weighted, in common clinical parlance, the FLAIR method refers to FLAIR T2-weighted images. The main advantage of FLAIR images is sensitivity to detect a broad array of pathologic processes and is specifically useful for the evaluation of white matter diseases in the brain. The archetypal example is multiple sclerosis (MS), which is characterized by periventricular white matter lesions, radially oriented to the bodies of the lateral ventricles (requiring both axial and sagittal FLAIR sequences for complete assessment) (**Fig. 22.1**; see **Fig. 22.6**).

Individual tissues have characteristic appearance on T1-weighted, T2-weighted, and FLAIR images. For example, cerebrospinal fluid (CSF) has a relatively long T1 and long T2 relaxation time and thus appears dark on T1-weighted images and bright on T2-weighted images (**Fig. 22.2A,B**). CSF appears dark on FLAIR images because these images are specifically calibrated to suppress CSF or "free" water (**Fig. 22.2C**). White matter in the adult is fully myelinated and appears slightly bright on T1-weighted images and dark on T2-weighted images (see **Fig. 22.2A,B**). Gray matter is brighter than white matter on T2-weighted images, whereas the reverse is true for T1-weighted images. Parenchymal hemorrhage can have a variety of appearances on T1- and T2-weighted images based on its components. In the brain, hemorrhage evolves predictably and its appearance can be used to infer its age. T2 prolongation (bright on T2-weighted images) correlates with hyperacute hemorrhage and late subacute hemorrhage, whereas T1 shortening (bright on T1-weighted images) correlates with early and late subacute hemorrhage. These characteristic appearances are summarized in **Table 22.1**.

Quantification of T1 and T2 Times

T1 and T2 relaxation time constants can be quantified to provide information of dynamic properties on a molecular level. Relaxation can also be measured during the application of a continuous radiofrequency pulse; in this case, the relaxation time constants are referred to as *T1-rho* and *T2-rho* (rho referring to a rotating reference frame used in the theoretical description). Magnetization transfer imaging as well as chemical exchange saturation transfer imaging are additional methods that rely on using a radiofrequency pulse to attenuate magnetization. These emerging methods are currently confined to the research setting but hold promise for future clinical applications.

Diffusion-Weighted Imaging

Diffusion-weighted imaging (DWI) is invaluable for the detection of early ischemic brain injury (**Fig. 22.3**). Like T1 and T2 processes, DWI creates image contrast by exploiting dynamic molecular properties, specifically translational diffusion, by applying multidirection diffusion sensitizing field gradients. In clinical practice, DWI is typically performed for water, although applications to other molecules have been reported. The "effect" of the diffusion gradient sequence is often quantified using a b-value. For adults, a b-value = 1,000 s/mm^2 is typically used, whereas b-value = 1,500 s/mm^2 is sometimes preferred in pediatric cases. In routine clinical practice, DWI is typically detected using an echo planar imaging (EPI) technique due to the speed of imaging. EPI is a gradient echo technique that can acquire the entirety of k-space within one excitation by interweaving frequency and phase dimensions.

Diffusion imaging is considered a quantitative technique, permitting the calculation of an apparent diffusion coefficient (ADC), which measures the extent to which the diffusivity of water is restricted from free diffusion, presumably due to structural barriers such as cell membranes or association of water with larger molecules that have lower diffusion coefficients. The most useful

FIGURE 22.1 Schematic representation of magnetic resonance. **A:** Magnetization *(red arrow)* aligns along the main magnetic field (B_0). A radiofrequency (*rf*) pulse generated by a transmit coil tips the magnetization from the aligned state by a flip angle (α). The magnetization precesses around the main magnetic field. The precessional motion results in a time-varying voltage in a radiofrequency receive coil, which is recorded as the magnetic resonance signal. **B:** While the magnetization precesses around the magnetic field, the decay of magnetization can be described by two separate exponential time constants. The magnetization vector can be decomposed into a longitudinal component parallel to the main magnetic field and a transverse component orthogonal to the main magnetic field. The T1 time describes the relaxation of magnetization back to the equilibrium-aligned state. The T2 time constant describes the decay of transverse magnetization. **C:** Images are created in magnetic resonance by applying multiple field gradients, which positionally encode the magnetic resonance signal. In this schematic of a patient's head, directly acquiring signal from each gradient direction allows encoding of the frequency dimension. Applying an additional increasing orthogonal gradient with every frequency encoding gradient allows encoding of the phase dimension. The signal from one gradient direction thus corresponds to one line of k-space. Once all of the lines of k-space are filled, a Fourier transform (FT) is used to make an image representation.

application of DWI is in acute stroke imaging (see Fig. 22.3A). This occurs most frequently in the setting of cellular bioenergetic failure and cytotoxic brain edema due to cerebral hypoxia/ischemia. Acute and early subacute infarcts display restricted diffusion and are easily detected as bright regions on DWI. Differentiation of acute infarcts from late subacute infarcts, both of which can appear bright on DWI (known colloquially as *T2 shine through*), can be accomplished by examination concurrent ADC image. Acute to early subacute infarcts truly demonstrate restricted diffusion and appear dark on the ADC image (see Fig. 22.3B). Subacute to chronic infarcts are bright on DWI due to T2 shine through and appear isointense to bright on the ADC image.

Other conditions including uncontrolled status epilepticus and prion diseases (eg, Creutzfeldt-Jacob disease) may demonstrate increased cortical DWI signal. Restricted diffusion can also be observed in hemorrhage and for tissues/neoplasms with high cellular density in the case of active inflammation and within the center of abscesses. DWI is specifically useful in the evaluation of brain tumors, where foci of restricted diffusion raise suspicion for an aggressive hypercellular tumor component, which may predate contrast enhancement.

Gradient-Recalled Echo and Susceptibility-Weighted Imaging

The primary clinical use of gradient-recalled echo (GRE) or susceptibility-weighted imaging (SWI) is sensitivity to the presence of small amounts of hemorrhage. SWI or GRE images

FIGURE 22.2 Normal T1-weighted, T2-weighted, fluid-attenuated inversion recovery (FLAIR), and inversion recovery (IR) images. **A:** Normal T1-weighted images of the brain and cervical spine. White matter is bright and gray matter is dark. Cerebrospinal fluid (CSF) signal is dark. **B:** Normal T2-weighted images of the brain and cervical spine. Gray matter is bright, and white matter is dark. CSF signal is bright. **C:** Normal FLAIR image of the brain and IR image of the cervical spine. On the FLAIR image, CSF signal is suppressed and appears dark; white matter is dark and gray matter is bright similar to a T2-weighted image. On the IR image of the cervical spine, fat is suppressed and there is increased contrast in the spinal cord.

TABLE 22.1 Usual Appearance of Normal Structures on T1-Weighted, T2-Weighted, FLAIR, DWI/ADC, and GRE or SWI Images

	T1-Weighted	T2-Weighted	FLAIR	DWI/ADC	GRE or SWI
CSF	Dark	Bright	Dark	Dark/bright	Bright
White matter or gray matter brighter	White matter brighter	Gray matter brighter	Gray matter brighter	Gray matter brighter/ white matter brighter	Variable
Acute infarct	Dark	Bright	Bright	Bright/dark	Variable
Hemorrhage	Bright if early or late subacute	Bright if hyperacute or late subacute	Variable	Variable	Dark
Edema	Dark	Bright	Bright	Variable/bright	Isointense

Abbreviations: ADC, apparent diffusion coefficient; CSF, cerebrospinal fluid; DWI, diffusion-weighted imaging; FLAIR, fluid-attenuated inversion recovery; GRE, gradient-recalled echo; SWI, susceptibility-weighted imaging.

FIGURE 22.3 Acute left middle cerebral artery (MCA) infarct. **A:** The diffusion-weighted imaging image shows bright signal in the left MCA territory. **B:** The corresponding apparent diffusion coefficient image shows dark signal confirming an acute or early subacute infarct. **C:** The corresponding fluid-attenuated inversion recovery image shows mild associated increased signal compatible with edema. **D:** Magnetic resonance angiography of the circle of Willis shows absent flow-related enhancement of the left distal M1 MCA segment *(arrow)* compatible with occlusion. Irregularity is also noted of the contralateral right M1 segment.

generate image contrast from differences in underlying magnetic susceptibility. Differences in susceptibility are interpreted to represent underlying paramagnetic or diamagnetic species and have important implications for characterizing tissue components such as calcification or iron content. SWI are slightly different from GRE images in that they depict intracranial vessels and are considered more sensitive than conventional GRE. Methods to quantify susceptibility are called *quantitative susceptibility mapping*. In the research setting, quantitative methods have applications in more accurate dating of hemorrhage, quantifying contrast agent enhancement, and in the evaluation for neurodegenerative disease associated with heavy metal deposition.

Gadolinium Contrast Enhancement

The use of intravenous paramagnetic contrast agents, typically gadolinium chelates, is invaluable in MRI. Enhancement is defined as increased T1 shortening following administration of contrast, and the concept is further developed in the context of magnetic resonance perfusion imaging. The presence of contrast enhancement in the brain parenchyma signifies a breakdown of the blood-brain barrier and has important implications for characterizing lesions from brain tumors and metastases to infectious and inflammatory etiologies (see Fig. 22.3D).

Several structures in the brain lack a blood-brain barrier such as the pineal gland and pituitary gland and normally enhance. Vascular enhancement is variable. Vessels are typically bright on *spoiled gradient echo*–type T1 postcontrast images but have a variable appearance on spin echo T1-type images, depending on flow rate and other imaging parameters. In the spine, enhancement can be observed in the epidural veins as well as the soft tissues. Dedicated magnetic resonance angiographic images may be necessary to characterize some vascular malformations, and conventional catheter angiography may be necessary to evaluate subtle vascular malformations.

In some situations, contrast-enhanced imaging may not be appropriate. Examples include contraindications to contrast such as prior severe allergic reactions or renal failure. In the setting of possible or prior allergic reaction, premedication with a standard steroid algorithm is necessary if the benefit of contrast to make a diagnosis outweighs the risks. Many imaging protocols such as for the evaluation of infarct, hypertensive hemorrhage, or acute spinal cord compression do not typically require postcontrast imaging. In the setting of an evolving infarct or parenchymal hemorrhage, contrast enhancement is sometimes seen and may in fact present a diagnostic dilemma in the absence of adequate clinical history.

Magnetic Resonance Angiography and Magnetic Resonance Venography

Vascular structures in the head and neck can be imaged noninvasively using MRI without the use of intravenous contrast agents as well as with contrast. Primary clinical applications include evaluating for stenosis, thrombosis, dissection, and aneurysm in the vascular structures of the head or neck. The *time-of-flight* (TOF) method relies on vascular flow to bring *fresh* unrelaxed spins into the imaging volume. As a result, vessels that contain flowing spins appear bright and are easily delineated. The *phase contrast* or *velocity encoding* method detects phase changes of spins moving through a gradient. *Contrast-enhanced magnetic resonance angiography* (MRA) methods rely on the T1 shortening effects of gadolinium chelates, which are directly injected intravenously. Appropriate timing of a bolus of contrast and imaging can provide individual arterial and venous phases.

In the neck, MRA is commonly used to assess the patency of the carotid and vertebral systems, although ultrasound (US) and neck computed tomography angiography (CTA) may be used as well. Specific protocols used at individual imaging facilities depend on the resources available and the pretest probability for abnormalities in the specific patient population. The American College of Radiology Appropriateness Criteria give equally high recommendations for carotid US, CTA, and MRA for screening in the setting of a physical exam finding, such as a carotid bruit.

FIGURE 22.4 Magnetic resonance angiography (MRA) and magnetic resonance venography. **A:** MRA of the neck delineates the carotid and vertebral arteries. Note the in-plane flow artifact *(arrow)* in the V3 segments of the vertebral artery. **B:** Contrast-enhanced MRA arterial phase shows resolution of flow artifacts. **C:** Normal MRA of intracranial vessels. **D:** MRA depicts a right supraclinoid carotid artery aneurysm *(arrow)*. **E:** Three-dimensional time-of-flight magnetic resonance venography depicts the dural venous sinuses. **F:** Velocity-encoded magnetic resonance venography of the dural venous sinuses.

However, in the setting of focal neurologic deficit, MRA and CTA are preferred over US.

Noncontrast MRA of neck, using two-dimensional and three-dimensional TOF methods may be sufficient to exclude hemodynamically significant carotid stenosis. One limitation of noninvasive TOF techniques, however, is turbulent or slow flow, which can lead to loss of signal and overestimate the degree of stenosis, leading to false-positive results. This is specifically true in the carotid bulb or the V3 vertebral artery segments, which are sensitive to flow artifacts (**Fig. 22.4A,B**). Contrast-enhanced MRA is considered the most sensitive noninvasive imaging method for the diagnosis of 70% to 99% internal carotid artery stenosis with meta-analytic estimates of sensitivity equal to 85% (95% CI, 69%-93%) and specificity equal to 85% (76%-92%). Furthermore, in cases of carotid or vertebral arterial dissection, subtle luminal changes may be better evaluated with additional T1-weighted or proton-density weighted fat-saturated images in addition to contrast-enhanced methods.

In the intracranial circulation, TOF MRA methods are well suited to evaluate for vessel patency and aneurysm formation (**Fig. 22.4C,D**). In the setting of screening for aneurysm, for example, when there is a positive family history, the American College of Radiology Appropriateness Criteria gives slightly higher recommendations to the use of CTA over MRA given the higher resolution of CTA and absence of flow artifacts.

The use of contrast-enhanced MRA methods is preferred when evaluating aneurysms following intervention, such as coiling or stenting or when evaluating cerebrovascular malformations. Time-resolved contrast-enhanced methods (in which successive acquisitions can provide multiple arterial and venous phases) in the head and neck are typically applied when the temporal profile of enhancement is important. Examples include differentiating low- from high-flow vascular malformations or slow flow from complete occlusion.

Magnetic resonance venography is used clinically to evaluate for patency of the dural venous sinuses in the setting of venous sinus stenosis or thrombosis. 2D TOF (**Fig. 22.4E**) and velocity encoding techniques (**Fig. 22.4F**) are typically employed. Time-resolved postcontrast methods are useful, however, when an abnormality is identified to differentiate flow artifacts or partial stenosis/occlusion from complete occlusion.

Outside of the head and neck, MRA can be applied to the spine to evaluate for vascular malformations. Lastly, although MRA and magnetic resonance venography are useful techniques, some subtle vascular malformations may only be identified on conventional catheter angiography, and this must be considered if there is the need to completely exclude an underlying vascular malformation.

MAGNETIC RESONANCE IMAGING ARTIFACTS

MRI is subject to a multitude of artifacts, which in general refers to image representations that are distortions of the true underlying anatomy. Artifacts can both introduce nonexistent structures or obscure anatomy. Artifacts can originate from any of the multiple steps in signal generation, acquisition, and processing in addition to the underlying properties of biologic tissues and patient cooperation.

Some of the most commonly encountered artifacts arise from motion, either due to voluntary or involuntary patient motion (**Fig. 22.5A**) or biologic flow phenomena such as in vascular structures or pulsation of CSF (**Fig. 22.5B**). Flow phenomena lead to either increased or decreased signal within vascular structures, similar to effects exploited in noncontrast TOF MRA. Patient motion or pulsating structures such as vessels result in ghosting-type artifacts in clinical images (**Fig. 22.5C**).

FIGURE 22.5 Magnetic resonance imaging artifacts. **A:** Motion artifact results in ghosting on a fluid-attenuated inversion recovery image. **B:** Flow artifact due to cerebrospinal fluid pulsations in the lateral ventricles *(arrow)*. **C:** Ghosting artifact due to pulsatile flow in the transverse sinuses *(arrow)*. **D:** Susceptibility artifact leads to increased signal in the frontal region due to failure of cerebrospinal fluid suppression. **E:** Corresponding susceptibility artifact due to dental hardware is shown on a T1-weighted image. **F:** Zipper artifact due to stray radiofrequency interference.

Ghosting artifacts also arise in EPI (called *N/2 ghosts*) due to distortions between successive echoes.

Susceptibility artifacts arise when there are distortions of the local magnetic field. This can be due to air-tissue interfaces or implanted metallic material. These artifacts are commonly encountered in the setting of dental hardware (such as fillings or braces), aneurysm clips, or spine fusion hardware. Usually, these artifacts lead to loss of signal in adjacent structures, but they may also result in increased signal, for example, in FLAIR imaging (Fig. 22.5D,E).

Aliasing artifacts are common when the field of view in the phase encoding dimension is too small; structures outside the field wrap within the image. It is important to note that these artifacts can arise from any phase encode direction.

Stray radiofrequency interference leads to so-called zipper artifacts (Fig. 22.5F). For this reason, MRI rooms are electrically shielded and must be operated with the door closed. Many additional artifacts are described in MRI, related to chemical shift effects, coil, and radiofrequency inhomogeneity.

CLINICAL MAGNETIC RESONANCE IMAGING

MRI attains significantly higher contrast between different biologic tissues compared to other cross-sectional imaging techniques such as computed tomography (CT) or US. For this

reason, MRI is considered the most precise and sensitive imaging modality for detecting CNS tissue pathology. Appropriateness criteria for MRI, CT, and other imaging modalities in various neurological conditions have been developed by the American College of Radiology. These are regularly updated and available at www.acr.org/Quality-Safety/Appropriateness-Criteria.

Approaches to imaging use in several common clinical scenarios—infarction, white matter disease and transverse myelitis (TM), and brain and intradural spinal cord tumors, are discussed in the following sections. Discussed throughout this text are suggested and typical uses of neuroimaging in the workup of a wide range of neurological diseases.

Cerebrovascular Disease

MRI has revolutionized stoke imaging. Acute infarcts are bright on DWI and display restricted diffusion on ADC images (see **Fig. 22.3**). Mass effect and vasogenic or cytotoxic edema can be evaluated on associated T2-weighted or FLAIR images. The presence of hemorrhage can be identified on SWI or GRE images. The size of the infarct can be quantified and the specific vascular territories involved can be delineated. Various scoring scales may be used to determine prognosis or indicate treatment based on imaging. Concurrently, performed vascular imaging can show causative vascular disease, such as stenosis, thrombosis, or dissection.

The approach to stroke imaging begins with close inspection of the DWI for increased diffusion-weighted signal relative to the background of normal structures. Once a lesion is identified, evaluation of the ADC image can confirm an acute or early subacute infarct, which is dark relative to background. Evaluation of the SWI or GRE images is used to look for evidence of hemorrhage or hemorrhagic conversion. It is important not to confuse hemorrhage with an acute infarct, both of which may show restricted diffusion. Additional sequences including T2 and FLAIR images are used to evaluate for mass effect, cytotoxic, and vasogenic edema. Some authors suggest that inspection of the concurrent FLAIR images may differentiate between acute and subacute infarcts when clinical information is incomplete or unavailable.

The specific structures involved in stroke and multiplicity of infarcts help to differentiate individual vascular territories from embolic-type infarcts and diffuse ischemia/hypoxia. Stroke imaging typically is performed in conjunction with vascular imaging such as MRA or CTA of the head and neck with attention specifically focused on determining if vascular occlusion is responsible for the infarct (see **Fig. 22.3D**). Perfusion imaging in stroke is sometimes performed to determine the size of the territory at risk and guide intervention. Spinal cord infarct may also be evaluated using the DWI sequence.

White Matter Disease

Abnormalities in the white matter are best identified on FLAIR images. The differential diagnosis of white matter disease includes demyelinating and dysmyelinating etiologies, vasculitic and vasospastic processes, infection and inflammatory processes, toxic/metabolic etiologies, edema, trauma, seizures, as well as neoplasm and hypoxic/ischemic processes including arterial and venous infarcts. Characterizing these processes and narrowing the differential diagnosis require concurrent integration of clinical information and a complete set of MRI sequences.

As an example, we discuss an approach to MS, an archetypal disease process with imaging abnormalities on brain and spine MRI (**Fig. 22.6**). The approach to MS begins with thorough

FIGURE 22.6 Multiple sclerosis. A: Characteristic white matter lesions of multiple sclerosis depicted on an axial fluid-attenuated inversion recovery image. **B:** Low signal intensity of the lesions on T1-weighted images suggests chronic lesions. **C:** Sagittal fluid-attenuated inversion recovery image depicts the radial orientation of white matter lesions characteristic of multiple sclerosis.

inspection of the FLAIR images for abnormal signal specifically involving the white matter. Supratentorially, lesions are typically identified in the periventricular, deep, and subcortical/juxtacortical white matter and corpus callosum, as well sometimes the basal ganglia, although cortical disease burden in MS is not well delineated on FLAIR imaging. Sagittal FLAIR images are invaluable for confirming subtle lesions on axially acquired sequences and for evaluating the corpus callosum. T2-weighted images are preferred for the evaluation of white matter lesions in the brainstem and cerebellar white matter due to artifacts in the posterior fossa on FLAIR images. After lesions are identified, their acuity is estimated based on associated diffusion abnormality and contrast enhancement, both of which would suggest acute demyelinating lesions. Finally, because MS patients undergoing treatment may be immunosuppressed, it is important to evaluate for superimposed infection such as progressive multifocal encephalopathy.

In the spine, the approach to MS concentrates on using T2-weighted images and IR T2-weighted images. IR T2-weighted images are similar to FLAIR images in that they also employ an inversion pulse; however, they are timed not to suppress CSF signal but rather to increase the conspicuity of lesions and suppress signal from fat. In contradistinction to the brain, spinal cord white matter is located peripherally to the central gray matter. Therefore, MS lesions within the spinal cord tend to be peripherally located (best seen on axial images) and span less than two vertebral body segments (on sagittal images). They are most frequently located within the cervical cord. As in the brain, the presence of contrast enhancement is used to identify acute lesions. It is important to remember that patient symptoms may not be due to demyelinating lesions in the spinal cord but rather to degenerative changes, such as disk herniations.

Brain and Spinal Cord Tumors

Tumors are defined by the presence of mass effect, where normal structures are displaced or infiltrated and display abnormal signal characteristics including postcontrast enhancement. Despite common belief, contrast enhancement does not always correlate with World Health Organization tumor grade. For example, both grade I pilocytic astrocytoma and grade IV glioblastoma typically display postcontrast enhancement. On the other hand, grade III anaplastic astrocytoma may not display contrast enhancement. FLAIR imaging is indispensable in brain tumor imaging because FLAIR imaging demonstrates nonenhancing tumor components but also associated mass effect and edema (Fig. 22.7). One of the main problems in evaluating brain tumors is distinguishing tumor recurrence (progression) from posttreatment changes (pseudoprogression). For this reason, tumor imaging typically entails advanced MRI methods such as magnetic resonance perfusion imaging and magnetic resonance spectroscopy (MRS), in addition to correlation with other modalities such as nuclear medicine ^{18}F-fluorodeoxyglucose positron emission tomography or thallium single-photon emission computed tomography.

The approach to assessment of brain tumors begins with localization of the lesion in the intra-axial or extra-axial space. Subsequent evaluation of mass effect and definition of the mass on T1-weighted, T2-weighted, FLAIR, or postcontrast images is performed. The adjacent parenchyma is evaluated for associated edema or infiltration. Diffusion-weighted images are used to evaluate associated ischemic changes or hypercellular components of the tumor. SWI or GRE images are used to evaluate for associated hemorrhage or calcifications. Given the heterogeneity of brain tumors, the location, appearance, signal characteristics, enhancement, or comparison to prior studies are all integrated to arrive at a differential diagnosis.

Similar to brain tumors, assessment of intradural spinal cord tumors begins with localization of the lesion in the intramedullary (intrinsic to the spinal cord) or extramedullary space (extrinsic to the spinal cord). Intradural, intramedullary lesions are generally T2 hyperintense with expansion of the cord and characteristically enhance. The primary differential diagnosis for intradural intramedullary lesion includes ependymoma or astrocytoma. Ependymomas arise from the central canal ependymal cells and thus tend to occur centrally within the cord and cause symmetric diffuse cord expansion. They are more common in adults and commonly involve the cervical and/or thoracic cord.

FIGURE 22.7 Glioblastoma. **A:** Post–contrast-enhanced image shows a large enhancing mass with central necrosis. **B:** Fluid-attenuated inversion recovery image depicts the associated white matter abnormality compatible with a combination of edema and nonenhancing tumor. **C:** Apparent diffusion coefficient image shows restricted diffusion in components of the tumor suggestive of increased cellular density.

Spinal astrocytomas are more common in young adults and children and occur slightly more commonly in the thoracic than cervical cord. Astrocytomas arise from the cord parenchyma and therefore are typically eccentric or exophytic with patchy enhancement as opposed to ependymomas, which often demonstrate avid focal enhancement with hemorrhage and/or peritumoral cysts. The primary differential diagnosis for intradural extramedullary lesion includes meningioma versus peripheral nerve sheath tumor (schwannoma or neurofibroma).

Transverse Myelitis

TM is characterized by hyperintense T2 signal within the spinal cord. The differential diagnosis includes demyelinating process such as MS, tumor such as astrocytoma, vascular ischemia/cord infarct, or postinfectious/inflammatory etiology such as acute disseminated encephalomyelitis. The differential diagnosis of TM can be further narrowed by the clinical history, laboratory and lumbar puncture results, and imaging appearance. On sagittal imaging, if the T2 signal abnormality typically extends at least three vertebral body segments, it is termed *longitudinally extensive TM*, which is characteristic of demyelination secondary to neuromyelitis optica. Neuromyelitis optica is diagnosed by the major criteria of longitudinally extensive TM and optic neuritis without evidence of sarcoid, vasculitis, lupus, or Sjögren syndrome. Additionally, the cross-sectional region of involvement within the cord on axial imaging is evaluated when refining the differential diagnosis.

ADVANCED MAGNETIC RESONANCE IMAGING METHODS

Functional Magnetic Resonance Imaging

Functional magnetic resonance imaging (fMRI) refers to the use of magnetic resonance for the localization of cerebral activation. The most commonly employed technique takes advantage of hemodynamic coupling of cerebral activation to indirectly infer cerebral activation. The blood oxygen level–dependent contrast mechanism results from a relative increase in the concentration of oxyhemoglobin (a paramagnetic species) compared to deoxyhemoglobin (a diamagnetic species) in response to cerebral activation. This change can be detected using rapid MRI sequences typically employing gradient echo sequences sensitive to T2* contrast, allowing cerebral activation to be imaged in the brain. Some authors have proposed using DWI to map cerebral activation but this is not common.

fMRI can be performed in conjunction with specific task paradigms (Fig. 22.8A,B). This type of fMRI has current clinical applications for mapping the cortical location of known cognitive and motor functional units and has specific use in presurgical and pretherapeutic planning. Examples include mapping the primary motor and visual cortices or localizing language activation areas.

In the research setting, the technique has been applied to monitor a variety of psychiatric disorders. When acquired without a specific task paradigm, the technique is referred to as *resting state fMRI*, which maps connectivity features of the so-called default-mode network.

Diffusion Tensor Imaging

Diffusion tensor imaging (DTI) is a technique that can quantify the directional dependence of diffusion of water. Clinically, DTI is most commonly applied to assess the integrity of white matter tracts (Fig. 22.8C). Normal white matter tracts are densely packed, which creates an anisotropic environment. Diffusion perpendicular to white matter tracts is relatively hindered compared to diffusion parallel to white matter tracts. Therefore, measuring the direction of greatest diffusion will estimate the dominant orientation of white matter tracts. Measuring multiple directions of diffusion can subsequently be used to define a diffusion tensor. The diffusion tensor information can then be postprocessed to generate images with white matter tracts.

FIGURE 22.8 Functional magnetic resonance imaging (fMRI) and diffusion tensor imaging. **A:** Preoperative fMRI showing activation of primary motor cortex during a motor task in a patient with a left frontal neoplasm. **B:** Preoperative fMRI showing activation of left frontal language processing area during a verb generation task. **C:** Fiber tracking performed based on diffusion tensor data showing displacement of the left frontal tracts by the left frontal mass.

More advanced approaches, such as Q-ball and diffusion spectrum imaging, provide a more general description of diffusion and have improved performance in resolving crossing white matter fibers. The current clinical application of DTI is definition of white matter tracts in presurgical and pretherapeutic planning. A multitude of applications of DTI to variety of neurologic conditions including stroke, MS, dementia, and traumatic brain injury primarily reside in the research setting. In part, this is due to lack of standardization of acquisition and postprocessing techniques as well as data lacking on clinical use, heterogeneity of findings across a population, and effect on patient outcomes.

Magnetic Resonance Spectroscopy

MRS is considered an advanced imaging technique within MRI, although it is an integral part in the formation of anatomic magnetic resonance images. In the absence of an applied field gradient, different nuclei can be resolved by their chemical shift. MRS in clinical practice typically refers to spatially selective acquisition (single or multiple voxel) of proton spectra, where care has been taken to suppress the dominant water resonance, thus increasing sensitivity for the resonances of small molecules. In the brain, the most commonly observed resonances belong to *N*-acetylaspartate (2.0 ppm—interpreted to signify normal neuronal tissue), creatine (3.0 ppm—interpreted to signify energy stores), choline (3.2 ppm—interpreted to signify components of the cell membrane and myelin), and lactate (doublet at 1.3 ppm—interpreted to signify anaerobic metabolism) (**Fig. 22.9**). The lactate doublet resonance corresponding to the lactate methyl protons is inverted at an echo time of 144 ms compared to 288 ms due to J-coupling effects with the lactate methine proton.

Additional metabolites such as inositol/myoinositol (interpreted as a marker of astrocytes and astrogliosis seen in MS lesions), glutamate/glutamine, and several amino acids such as alanine (described in meningiomas) and glycine can also be observed. The relative amplitude of the resonance peaks reflects the relative concentrations of metabolites; however, it should be noted that in general, relaxation effects may alter resonance amplitudes, highlighting attention to the TE. In general, more metabolites are seen with a shorter TE. In routine clinical practice, spectroscopy is often used as a problem-solving technique, for example, in an attempt to differentiate tumor recurrence from posttreatment effects (higher choline-to-creatine ratios tend to be observed with recurrent brain tumors than radiation necrosis; **Fig. 22.10C**) or to evaluate for inborn errors of metabolism such as mitochondrial disorders and leukodystrophies (the presence of a lactate peak may signify a mitochondrial disorder such as mitochondrial encephalomyelopathy, lactic acidosis, and stroke). MRS has also been used to directly observe 2-hydroxyglutarate, a metabolite that accumulates in isocitrate dehydrogenase mutant glioblastoma tumors, and thus constitutes a biomarker for isocitrate dehydrogenase status in glioma.

Magnetic Resonance Perfusion Imaging

Magnetic resonance perfusion is a method of quantifying blood flow through biologic tissues. The method is usually applied to the brain but has been extended to other parts of the body including the spine. The relevant measures include measurement of cerebral blood volume, cerebral blood flow, and mean transit time.

This is achieved in MRI using a *first-pass* or *bolus*-tracking method that records the signal reduction that occurs when rapidly repeated images are acquired during the first passage of an intravascular bolus of paramagnetic contrast, usually a gadolinium chelate. The images produced are called *perfusion-weighted images* or *dynamic susceptibility contrast images*. Gradient echo images with EPI-type detection are usually used because they provide the ability to image very rapidly to track the contrast bolus.

FIGURE 22.9 Magnetic resonance imaging spectroscopy. **A:** Diffusion-weighted imaging shows an acute infarct in the right superior frontal lobe. **B:** Voxel *(square)* is placed in the right superior frontal image on the corresponding fluid-attenuated inversion recovery image. **C:** Magnetic resonance spectroscopy performed at an echo time of 144 ms shows choline, creatine, and *N*-acetylaspartate (NAA) resonances with relative decrease of the NAA resonance. An inverted lactate doublet is present compatible with anaerobic metabolism in the setting of an infarct.

The time course of the signal change during the passage of the bolus can be used to obtain the cerebral blood volume (CBV), mean transit time (MTT), and their ratio, the cerebral blood flow (CBF = CBV / MTT). Because of the technical difficulty in measuring the arterial input function of the contrast bolus, perfusion maps are semiquantitative and are best interpreted as relative rather than absolute perfusion values (relative cerebral blood volume [rCBV], relative mean transit time [rMTT], and relative cerebral blood flow [rCBF]). If the arterial input function is known, then a measure of permeability of the extravascular-extracellular space known as *k-trans* can be calculated. Algorithms exist in clinical practice for quantifying the permeability of tissues to contrast (called *leakage*) from modeling of the perfusion time course without knowledge of the exact arterial input function.

Magnetic resonance perfusion can be performed without contrast with the arterial spin labeling (ASL) method. Similar to

FIGURE 22.10 Magnetic resonance perfusion imaging and magnetic resonance spectroscopy in recurrent high-grade glioma. **A:** Post–contrast-enhanced image showing abnormal enhancement *(red square)* in the posterior right parietal region. **B:** Magnetic resonance perfusion image shows a focus of increased relative cerebral blood volume *(red square)* suggestive of recurrent tumor. **C:** Magnetic resonance spectroscopy at a time to echo of 288 ms shows elevated choline and decreased *N*-acetylaspartate resonances suggestive of recurrent tumor. A lactate doublet is present.

TOF MRA, the ASL method depends on inflow of spins through vessels. ASL may provide more quantitative information without the need for arterial input functions but is less widely available than contrast bolus tracking methods.

Clinical applications of magnetic resonance perfusion include cerebrovascular disease. In cases of stroke or vasospasm, measures of perfusion delay, such as MTT, are sensitive indicators of small reductions in cerebral perfusion that can delineate relatively hypoperfused vascular territories. In this way, magnetic resonance perfusion is similar to CT perfusion methods but can be performed without ionizing radiation and permits direct correlation with other magnetic resonance images. Outside of cerebrovascular disease imaging, clinical applications of magnetic resonance perfusion include brain tumors and metastases. These applications focus on assessment of CBV, which correlates with histologic tumor grade and characterizes response to treatment of the tumor (Fig. 22.10A,B).

EMERGING MAGNETIC RESONANCE IMAGING METHODS

Recent advances in MRI aim to drastically improve the resolution of images and speed of imaging as well as to significantly extend clinical applications. The emergence of high field (>7 T) imaging systems promises improvements in signal to noise and image resolution as well as functional imaging. Similarly, improvements in imaging speed have been a constant focus since the inception of MRI. Recent advances rely on undersampling and subsequent reconstruction using nonlinear methods. One of the most popular of such methods called *compressed sensing* holds promise for implementing near real-time imaging, especially when combined with methods to improve signal to noise.

Although magnetic resonance is a very powerful technique to study structure and dynamic processes on a molecular level, its application to biologic systems is primarily limited by its inherent low signal to noise. As a result, low-concentration molecules involved in metabolism and other cellular functions are essentially inaccessible by conventional techniques. This limitation is primarily evident in MRS, where multidimensional experiments could in theory characterize a multitude of metabolites, provided there was sufficient signal to noise. The goal of emerging methods called *hyperpolarization* (HP) is to increase nuclear spin polarization and thus drastically increase signal to noise. A primary application of HP-MRI is the study of in vivo transient interactions through HP of small metabolites suited to probing varied processes such as metabolism and oxidative stress or as agents of perfusion. HP-MRI is a promising technique for combining the intrinsic biologic tissue contrast, temporal and

chemical shift resolution, as well as sensitivity to dynamic processes of magnetic resonance with molecular imaging.

Perhaps the most important advancement in clinical imaging comes from contemporary advances in information technology and quantitative image-processing methods. The availability of electronic medical records and digitally archived images has permitted the correlation of imaging features with molecular pathology and development of a new field of *radiogenomics*. This field is predicated on correlation of quantitative image analysis features with molecular markers and information pertaining to patient diagnosis, prognosis, and treatment response available within the electronic medical record. This revolution in medicine embraces the heterogeneity of pathologic processes and individual responses in the patient population and seeks to tailor therapeutics for maximal efficacy.

23 Positron Emission Tomography and Single-Photon Emission Computed Tomography

William Charles Kreisl

KEY POINTS

1. Positron emission tomography (PET) and single-photon emission computed tomography (SPECT) imaging use radionuclide decay to measure a specific biologic target or phenomenon.
2. [^{18}F]Fluorodeoxyglucose PET and perfusion SPECT may be useful in staging brain tumors, identifying seizure foci in epilepsy patients, and identifying patterns of neurodegeneration in dementia patients.
3. Ioflupane ^{123}I SPECT may be useful in distinguishing parkinsonism from essential tremor.
4. Amyloid and tau PET imaging may be used in select patients to aid in diagnosis of dementia.

INTRODUCTION

Molecular imaging is used in the clinical practice of nuclear medicine and in medical research to better understand the biochemical processes that underlie human disease. Two examples of molecular imaging are positron emission tomography (PET) and single-photon emission computed tomography (SPECT). In both PET and SPECT, patients are administered a radioactive compound with a pharmacokinetic behavior that targets a molecular pathway related to the pathology of a certain disease.

PET and SPECT allow highly sensitive and selective measurement of specific biologic changes in the human body. Agents are administered in amounts too small to cause pharmacologic effects ("trace" doses) so as to avoid perturbation of the biochemical pathway being studied. Many radioactive compounds used in PET and SPECT reversibly bind to a target protein via ligand-receptor kinetics. In these cases, the radioactive ligand is referred to as a *radioligand*. However, some radioactive compounds used for PET or SPECT do not bind a target protein. For example, oxygen-15 water ([^{15}O]H_2O) is used to measure perfusion because the uptake of this compound reflects the flow of blood into a given tissue. A [^{15}O]H_2O PET scan therefore does not measure the binding of water to any receptor but rather it traces the flow of blood to different tissues (**Fig. 23.1**). In this case, the term *radiotracer* is more appropriate. A broader term that applies to all compounds used with PET or SPECT is *radiopharmaceutical*, reflecting that the radioactive compounds used in molecular imaging are given the same regulatory considerations as drugs.

FIGURE 23.1 Example of [^{15}O]H_2O perfusion scan. The patient with Alzheimer disease has lower cerebral perfusion in the parietal cortex bilaterally *(arrows)* than the age-matched cognitively normal control subject. (Image courtesy of Robert Innis and William Charles Kreisl, Molecular Imaging Branch, National Institute of Mental Health.)

BASIC PRINCIPLES

Both PET and SPECT employ the physical phenomenon of radioactive decay, which occurs in radionuclides that are unstable due to incompatible number of protons and neutrons or excess energy.

In PET imaging, radionuclides are proton rich and, as a result, undergo decay and emission of a positron. An example of a radionuclide is carbon-11 (^{11}C), which has six protons and five neutrons. Unstable due to the greater number of protons than neutrons, ^{11}C undergoes a decay event in which a proton is converted to a neutron and the nucleus emits a positron and a neutrino. The positron will then zigzag around the vicinity of the decay event, losing energy as it collides with electrons of neighboring atoms, until it comes almost to rest and combines with an electron. Because a positron and electron are of equal mass but opposite charge, this event results in an annihilation encounter, with two 511-keV gamma rays (photons) emitted at about 180 degrees from each other. Other examples of positron-emitting radionuclides used for PET are fluorine-18 (^{18}F), oxygen-15 (^{15}O), and nitrogen-13 (^{13}N).

In SPECT imaging, radionuclides exist in a metastable state and decay from their excited state to ground state, resulting in emission of a single photon. The gamma-emitting radionuclides technetium 99m (^{99m}Tc) and iodine-123 (^{123}I) are commonly used for SPECT.

RADIOPHARMACEUTICALS AND SELECTION OF RADIONUCLIDES

Radionuclides are combined with a pharmaceutical through a series of synthetic steps to create a radiopharmaceutical. Radiopharmaceuticals are administered either intravenously or orally, and once in the biologic system, they interact with different molecules based on the kinetic properties of the pharmaceutical to which the radionuclide is attached. The radionuclide will then undergo nuclear decay as described earlier, ultimately resulting in the emission of two photons in the case of PET and a single photon in the case of SPECT. The radiation exposure to the patient is a function of the radionuclide used and the amount of radiopharmaceutical administered. Radionuclides with longer half-lives (eg, ^{18}F, $t_{1/2}$ = 110 min) result in larger exposure than those with shorter half-lives (eg, ^{11}C, $t_{1/2}$ = 20.5 min). However, the advantage of radiopharmaceuticals with long half-lives is that they may be synthesized offsite and delivered to medical facilities, providing greater availability for clinical use. Use of radiopharmaceuticals with short half-lives is limited to facilities capable of onsite synthesis.

DETECTION, ACQUISITION, AND DISPLAY OF SIGNAL

When radiopharmaceutical decay events occur inside a PET or SPECT scanner, crystals in a scintillation detector absorb the photons and then emit pulses of light that are then amplified, sorted, and registered as a count. The sum of these counts creates a tomographic map of all the decay events that occur within the view of the scanner. The result is an image that represents the different densities of radioactivity throughout the tissues captured by the scanner. The basis of PET and SPECT imaging is that the majority of decay events occur in proximity to where the radiopharmaceutical is acting on the molecular target of interest. The sensitivity of PET and SPECT is a function of the fraction of emitted photons that contribute to the total image. In PET, coincidence detection of the pair of photons that are emitted per decay event allows greater efficiency than in SPECT, which captures only the single photons that approach the detector at certain angles. Therefore, PET is generally more sensitive than SPECT and is more frequently used for quantitative imaging, although absolute quantitation has been reliably attained with SPECT.

The PET and SPECT images reflect only the amount of radioactivity detected by the scanner. The scanner cannot distinguish between sources of radioactivity (which radionuclide or which radiopharmaceutical was administered). Therefore, sufficient time (at least six half-lives of the radionuclide) must pass between consecutive scans on the same subject; otherwise, the second scan will be contaminated from residual signal from the first. In addition, once injected, radiopharmaceuticals are broken down by enzymes in the liver and other tissues (including brain in some instances) leading to the generation of radiolabeled metabolites. If these metabolites are generated in the brain or cross from the blood into the brain, they will contribute to the total signal in the resulting images, potentially confounding accurate quantification. For this reason, using radiopharmaceuticals that do not generate radiometabolites that cross the blood-brain barrier is beneficial. Another problem is cross-selectivity and nonspecific binding. If a radiopharmaceutical binds more than one receptor in the brain, the resulting image will overestimate the density of the intended target. As radiopharmaceuticals must be lipophilic to cross the blood-brain barrier, they often bind nonspecifically to lipids throughout the brain. Both specific binding to the target protein and nonspecific binding contribute to the signal seen on the resulting image. However, only the specific binding component represents the density of the target protein. Therefore, a high ratio of specific to nonspecific binding is favorable for reliable PET and SPECT measurements.

CLINICAL APPLICATIONS

The radiopharmaceuticals in **Table 23.1** are currently approved by the U.S. Food and Drug Administration (FDA) for indications in clinical neurology.

The sensitivity of PET and SPECT is ideal for measuring spe-

TABLE 23.1 Neurologic Applications of PET and SPECT Imaging

PET Radioligand	Molecular Target/Mechanism Studied	Clinical Indication
[^{18}F]Fluorodeoxyglucose (FDG)	Glucose metabolism	• Tumor staging and evaluation • Epilepsy • Distinguishing Alzheimer disease from frontotemporal dementia
[^{18}F]florbetapir (*Amyvid*) [^{18}F]flutemetamol (*Vizamyl*) [^{18}F]florbetaben (*Neuraceq*)	Fibrillar amyloid plaques	Diagnosis of Alzheimer disease
[^{18}F]flortaucipir (*Tauvid*)	Paired helical filament tau	Estimate the density and distribution of aggregated tau neurofibrillary tangles in adult patients with cognitive impairment who are being evaluated for Alzheimer disease.
SPECT Radioligand	**Target**	**Clinical Indication**
Ioflupane ^{123}I (DaTscan)	Dopamine transporter	Distinguishing neurodegenerative parkinsonism from essential tremor
[^{99m}Tc]HMPAO (*Neurolite*) [^{99m}Tc]ECD (*Ceretec*)	Cerebral perfusion	• Stroke • Epilepsy • Dementia

Abbreviations: ^{99m}Tc, technetium 99m; ECD, ethyl cysteinate dimer; FDG, fluorodeoxyglucose; HMPAO, hexamethyl-propylene amine oxime; PET, positron emission tomography; SPECT, single-photon emission computed tomography.

cific biochemical changes in the brain. However, the expense of molecular imaging limits its cost-effectiveness in clinical practice. This is particularly true when diagnoses can be made with reasonable confidence using other techniques or when the results of molecular imaging are unlikely to alter management of the patient. Therefore, PET and SPECT imaging have a limited role in clinical neurology. However, as new disease-modifying therapies for neurologic disorders become available, molecular imaging may provide a critical role in predicting and monitoring treatment response.

Glucose Imaging

[^{18}F]Fluorodeoxyglucose (FDG) is structurally identical to D-glucose except for the substitution of ^{18}F for a hydroxyl group at the 2′ position. Like glucose, FDG is taken up by cells using the glucose transporter and phosphorylated by hexokinase in the first step of glycolysis. Once phosphorylated, FDG becomes charged and therefore trapped in the cell. Lacking a 2′ hydroxyl group, [^{18}F]FDG-6-phosphate cannot undergo further metabolism. The concentration of FDG in cells therefore reflects the metabolic activity, both in taking up FDG via active transport and its phosphorylation during glycolysis.

Positron Emission Tomography Using [^{18}F]Fluorodeoxyglucose in Epilepsy

Although the most widely used PET radiopharmaceutical for clinical applications, FDG is only approved by the FDA for cancer staging and evaluation, measuring myocardial viability in patients with coronary artery disease, and detecting seizure foci in epilepsy patients. In the case of epilepsy, during a seizure, the cells at the focus of epileptic activity will have greater metabolic demand and take up more FDG than surrounding cells. Therefore, focal increase in FDG-PET signal can identify epileptic foci if the scan is performed during a seizure. Between seizures, the epileptic focus often has lower metabolic demand than normal brain tissue, as repeated seizures are associated with decrement in baseline function. Therefore, interictal FDG-PET may show an area of hypometabolism (reduced FDG uptake) in the seizure foci. These findings may aid the neurosurgeon in planning surgical excision for treatment of refractory epilepsy.

Positron Emission Tomography Using [^{18}F]Fluorodeoxyglucose in Dementia

The FDG-PET is often used off-label to assist in diagnosis of dementia, particularly when attempting to distinguish Alzheimer disease from frontotemporal dementia (Fig. 23.2). Patients with Alzheimer disease typically show a signature pattern of FDG hypometabolism in the temporal and parietal cortices bilaterally. Patients with frontotemporal dementia, in contrast, show early hypometabolism in the prefrontal cortex, particularly in behavioral variant frontotemporal dementia. These differing patterns of hypometabolism may aid the clinician in making the correct diagnosis, particularly when both behavioral and memory symptoms are present in the same patient. Although not FDA approved for this purpose, the Centers for Medicare & Medicaid Services provides reimbursement for FDG-PET when used for this indication.

Dopamine Imaging

Ioflupane ^{123}I (DaTscan) is a SPECT radiopharmaceutical that binds to presynaptic dopamine transporters (Fig. 23.3). Ioflupane ^{123}I is approved to aid clinicians in distinguishing tremor caused by neurodegenerative parkinsonian syndromes from that caused by essential tremor. In the former, loss of dopaminergic neurons that originate in the substantia nigra will result in fewer presynaptic dopamine transporters in the striatum. Patients with neurodegenerative parkinsonian syndrome will have reduced striatal signal on DaTscan, whereas a patient with essential tremor will have normal signal. DaTscan is commonly used off-label to help distinguish dementia with Lewy bodies from Alzheimer disease.

FIGURE 23.2 Using [^{18}F]fluorodeoxyglucose-positron emission tomography to distinguish Alzheimer disease from frontotemporal dementia. The Alzheimer disease patient on the left shows biparietal hypometabolism *(white arrows)*, whereas the frontotemporal dementia patient on the right shows bifrontal hypometabolism *(yellow arrows)*. (Image courtesy of Robert Innis and William Charles Kreisl, Molecular Imaging Branch, National Institute of Mental Health.)

Perfusion Imaging

[^{99m}Tc]-hexamethyl-propylene amine oxime (Neurolite) and [^{99m}Tc] ethyl cysteinate dimer (Ceretec) are SPECT radiopharmaceuticals approved as adjunct in detecting areas of abnormal cerebral perfusion in patients who have had a stroke. These SPECT

FIGURE 23.3 Left: a normal Ioflupane ^{123}I (DaTscan) single-photon emission computed tomography (SPECT) scan. The SPECT signal is concentrated in the striatum bilaterally, reflecting normal density of presynaptic dopamine transporters and intact nigrostriatal dopaminergic innervation. **Right:** an abnormal DaTscan showing reduced tracer uptake in striatum bilaterally, worse on the right side of the brain. This abnormal scan represents reduced density of presynaptic dopamine transporters due to nigrostriatal neurodegeneration.

scans are often performed after vasodilatory challenge with acetazolamide to measure cerebrovascular reserve. The SPECT perfusion imaging can also be used to identify ictal foci in patients with seizures or status epilepticus. Because reduced blood flow typically localizes to neurodegeneration, perfusion SPECT may also be used to distinguish different types of dementia.

Amyloid Imaging

Several PET radiopharmaceuticals that label the β-amyloid plaques found in Alzheimer disease have been developed (Fig. 23.4). These compounds bind to amyloid in neuritic plaques more strongly than diffuse plaques and do not label soluble amyloid at all. As studies suggest that amyloid plaque deposition occurs years prior to symptom onset, amyloid PET may be of particular use in early diagnosis of Alzheimer disease to distinguish mild cognitive impairment caused by Alzheimer disease versus that caused by other entities. Because non-Alzheimer diagnoses such as cerebral amyloid angiopathy and dementia with Lewy bodies may be associated with amyloid deposition in brain, and up to one-third of older cognitively normal adults have incidental amyloid positivity on PET, a positive amyloid scan should not be taken as proof positive of an Alzheimer disease diagnosis. However, a negative scan is considered inconsistent with the known neuropathology of Alzheimer disease. The amyloid-detecting radiopharmaceutical [^{11}C]-Pittsburgh compound B has been widely used in Alzheimer disease research; however, the short half-life of ^{11}C makes its clinical use impractical. [^{18}F]Florbetapir (Amyvid), [^{18}F]flutemetamol (Vizamyl), and [^{18}F]florbetaben (Neuraceq) have longer half-lives and have been approved by the FDA to assist clinicians in the diagnosis of Alzheimer disease. In 2013, the Centers for Medicare & Medicaid Services decided not to provide coverage for amyloid PET imaging for diagnosis of Alzheimer disease, except for patients participating in certain studies under Coverage with Evidence Development program. The first such study (Imaging Dementia—Evidence for Amyloid Scanning), which included 11,409 Medicare beneficiaries with mild cognitive impairment or dementia, showed that use of amyloid PET resulted in change of management (eg, initiation of discontinuation of cholinesterase inhibitor therapy) in approximately 60% of patients. Use of amyloid PET was associated with change in clinical diagnosis from Alzheimer disease to non-Alzheimer disease in 25% of patients and from non-Alzheimer disease to Alzheimer disease in 10.5% of patients.

FIGURE 23.4 Example of amyloid positron emission tomography (PET) imaging. Two patients meeting clinical criteria for dementia underwent PET imaging with [^{18}F]florbetaben (Neuraceq). The image on the **left** shows radioligand binding in amyloid plaque–rich cortical areas, whereas the image on the **right** shows PET signal limited to nonspecific binding in white matter. These results suggest that the patient on the left has dementia due to underlying Alzheimer disease, whereas the patient on the right has dementia due to another cause.

To guide clinicians on when to order an amyloid PET scan on a patient, Appropriate Use Criteria have been proposed. In general, it was agreed on that amyloid PET imaging should be reserved for patients with cognitive complaints and objective evidence of impairment on testing, when the diagnosis is uncertain but Alzheimer disease is a diagnostic consideration. In addition, the result of the amyloid PET scan should be expected to change management, either in the decision to order additional diagnostic tests or in the decision to start or stop medications such as cholinesterase inhibitors. Persistent and unexplained mild cognitive impairment, atypical (eg, nonamnestic) presentation, etiologically mixed presentation, and dementia in an unusually young patient (less than 65 y of age) are examples when amyloid PET may be appropriate. Amyloid PET imaging in place of genetic testing for suspected autosomal dominant mutation carriers, in cognitively normal individuals, and for nonmedical use (eg, insurance coverage) are examples of inappropriate use. Clinical interpretation of amyloid PET imaging use a binary "positive" or "negative" designation. Therefore, amyloid PET imaging should not be used to determine dementia severity.

Tau Imaging

PET radiopharmaceuticals that bind to the paired helical filament tau that makes up the neurofibrillary tangles found in Alzheimer disease have recently been developed (Fig. 23.5). As of publication, one such radiopharmaceutical, [^{18}F]flortaucipir (*Tauvid*) has been approved in the United States to estimate the density and distribution of aggregated tau neurofibrillary tangles in adult patients with cognitive impairment who are being evaluated for Alzheimer disease. Other tau radiopharmaceuticals currently under research development include [^{18}F]MK-6240, [^{18}F]PI-2620, [^{18}F]APN-1607, [^{18}F]GTP1, and [^{18}F]RO948.

RADIOPHARMACEUTICALS CURRENTLY IN DEVELOPMENT WITH POTENTIAL FOR CLINICAL USE

Synaptic Density Imaging

Synaptic dysfunction or loss of synapses and the resultant aberrant signaling is implicated in several neurologic disorders including Alzheimer disease and epilepsy as well as schizophrenia and other psychiatric diseases. The synaptic vesicle glycoprotein 2A (SV2A), as the name implies, is a synaptic vesicle protein that mediates neurotransmitter release. The antiepileptic action of levetiracetam is thought to be due at least in part to its binding to SV2A. A growing number of radiopharmaceuticals, including [^{11}C]UCB-J and [^{18}F]SDM-8, is currently under development to measure SV2A density in vivo. These radiopharmaceuticals may have broad clinical applicability, particularly in psychiatric diseases that lack established biomarkers.

FIGURE 23.5 Example of tau positron emission tomography imaging. [^{18}F]MK-6240, which binds to paired helical filament tau tangles, shows no appreciable signal in a cognitively normal individual **(left)**. However, radioligand binding is evident in a patient with mild cognitive impairment, particularly in medial and lateral temporal cortices **(center)**. [^{18}F]MK-6240 signal is even more intense in the patient with Alzheimer disease dementia **(right)**.

Neurovascular Ultrasound 24

Tatjana Rundek

KEY POINTS

1. Neurovascular ultrasound is a noninvasive methodology that uniquely provides real-time information on neurovascular structure and function.
2. Major neurovascular imaging technologies (extracranial duplex ultrasound and transcranial Doppler) have been widely validated, indispensable technologies in stroke centers, and clinically indicated in stroke and other cerebrovascular and cardiovascular conditions.

INTRODUCTION

Neurovascular ultrasound is imaging technology that uses ultrasound to image structure and examine the function of the brain vasculature. Neurovascular ultrasound includes two major ultrasound imaging technologies: extracranial ultrasound (duplex ultrasound or color Doppler) and transcranial ultrasound (transcranial Doppler [TCD]). Together, these techniques provide a real-time, noninvasive, and comprehensive evaluation of the major brain-supplying arteries. Besides, these imaging technologies are repeatable and portable and therefore can be performed at bedside, emergency rooms, or at any other patient care settings. Extracranial Doppler and TCD have become an integral part of the evaluation of patients with cerebrovascular disease or in asymptomatic individuals at an increased risk of vascular disease. These technologies are also an integral part of primary and comprehensive stroke centers. The most established clinical situations for the use of neurovascular ultrasound include the early detection and characterization of extracranial and intracranial atherosclerosis and occlusive disease; the evaluation of cerebral hemodynamic consequences of proximal arterial occlusive disease; monitoring of response to treatment of acute or chronic occlusive atherosclerotic disease; the time course and reversibility of cerebral vasospasm after subarachnoid hemorrhage; the detection of cerebral emboli in patients with cardiac, aortic, and carotid disease; and selection of sickle cell patients for blood transfusion as an effective imaging technology in primary stroke prevention. Neurovascular ultrasound is often used to complement other neuroimaging technologies such as magnetic resonance angiography and computed tomography angiography (CTA). All of these neuroimaging techniques provide concordant results when performed in accredited laboratories. If discrepancies arise, conventional two-dimensional angiography may be indicated and in most institutions only if an immediate interventional revascularization procedure is considered.

EXTRACRANIAL ULTRASOUND (DUPLEX ULTRASOUND OR COLOR DOPPLER)

Extracranial ultrasound is the noninvasive method of screening the extracranial carotid and vertebral arteries (VAs) for an atherosclerotic disease and detecting and monitoring structural and hemodynamic changes in existing extracranial atherosclerotic or other inflammatory or noninflammatory vascular diseases. Extracranial ultrasound is the technology with the lowest risk and cost. It provides real-time imaging of anatomy, physiology (hemodynamics), and pathophysiology of the extracranial circulation. Extracranial ultrasound is used in the risk stratification of patients with symptomatic or latent cerebrovascular disease as well as in asymptomatic patients to detect the presence of carotid stenosis and to evaluate other carotid artery phenotypes, including carotid plaque size, plaque echomorphology, intima-media thickness (IMT), and carotid stiffness. It is an ideal technology to frequently follow the existing extracranial vascular disease and monitor the status of the vasculature after interventional therapies such as carotid stenting or endarterectomy.

Imaging modes of extracranial ultrasound include the *brightness* or *B mode*, *color* or *C mode*, *Doppler* or *D mode*, *power mode* or *P mode*, and *motion* or *M mode* (Table 24.1). An ultrasound system that combines the B and D modes is called *duplex ultrasound*, and if B, C, and D modes are combined, it is called *triplex* or

TABLE 24.1 Ultrasound Imaging Modalities

Ultrasound Modality (Mode)	Abbreviation	Mode Display
Brightness mode	B mode	Echoes are displayed in various levels of gray.
Color mode	C mode	The Doppler signal of blood flow velocities is displayed in color.
Doppler mode	D mode	Shift in echoes is obtained from the moving blood particles and displayed as a Doppler spectrum of blood flow velocities.
Power mode	P mode	The Doppler signal of blood flow is displayed independent of the angle of insonation and is therefore magnified.
Motion mode	M mode	Motion of interfaces is recorded along the depth axis.

FIGURE 24.1 Normal appearance of carotid arteries on B mode and classic carotid artery (CA) waveforms on D mode.

color Doppler. All current ultrasound systems are equipped with a combination of all of these imaging modes.

Normal carotid arteries appear straight with bifurcation oriented toward the head (Fig. 24.1), without any pathologic processes in the arterial lumen (black) or in arterial wall (white) on B-mode imaging, and with classic arterial waveforms with blood flow directions toward the head on D-mode.

Carotid Ultrasound Criteria for Detection of Carotid Stenosis

Carotid stenosis is traditionally defined as stenosis greater than 50% by carotid ultrasound criteria. The most important ultrasound measures in assessing carotid stenosis are peak systolic velocity, end-diastolic velocity, and velocity ratios. These are applied in prestenotic, stenotic, and poststenotic regions. The degree of stenosis is also assessed visually and measured from grayscale ultrasound images and cross-checked with color Doppler imaging, which can guide Doppler velocity determination in order to select the most critical part of stenosis for Doppler velocity examination. The examples of carotid ultrasound criteria for the degree of carotid stenosis are widely available. The Society of Radiologists in Ultrasound has published multidisciplinary consensus on diagnostic criteria to grade the internal carotid artery (ICA) stenosis using Duplex ultrasound (Table 24.2) LEVEL 2.[1] These criteria can be used as a template for new vascular laboratories as well as to validate individual laboratory criteria for the estimation of carotid stenosis (Fig. 24.2). Because of variability in Doppler velocity measurements and standards, there are discrepant criteria for Doppler parameters of carotid stenosis. Each carotid ultrasound laboratory must, therefore, develop and validate its own criteria to grade carotid stenosis. These parameters must be validated with other imaging modalities and/or surgical findings and an ongoing quality control program must be implemented.

Assessment of Carotid Artery After Carotid Endarterectomy and Stenting

Carotid imaging shows changes in the carotid artery wall after successful carotid surgery or stenting. Special attention needs to be paid to the evaluation of the arterial wall changes at the edges of carotid reconstruction where incomplete plaque removal, intimal flap or step, and residual stenosis can be detected. In addition, Doppler velocities may show values above normal through the reconstructed part of the artery likely due to flow remodeling or increased stiffness in the stented segments. If peak systolic velocities at maximal narrowing in the reconstructed artery are greater than 150 cm/s and the peak systolic ratio between stenotic and prestenotic (or prestented) segment is greater than 2, then significant restenosis likely occurred (Fig. 24.3).

Sensitivity and Specificity of Duplex Ultrasound in Detecting Carotid Stenosis

Extracranial ultrasound is accurate and reliable in detecting carotid stenosis. The positive predictive value (PPV) of carotid ultrasound as compared to conventional angiography is 82% to 97%. In a large meta-analysis of 17 studies comparing carotid ultrasound with carotid angiography, carotid ultrasound had a pooled sensitivity of 86% (95% confidence interval [CI], 84%-89%) and a pooled specificity of 87% (95% CI, 84%-90%) for carotid stenosis LEVEL 2.[2] For diagnosis of occlusion, carotid ultrasound had a sensitivity of 96% (95% CI, 94%-100%). Although there can be considerable variation in the accuracy of duplex scanning among laboratories, accreditation programs such as Intersocietal Accreditation Commission set standards for performance and accuracy of vascular testing using most current validated and published data.

TABLE 24.2 The Society of Radiologists in Ultrasound Multidisciplinary Consensus Criteria for Carotid Stenosis[a]

Degree of Stenosis	ICA PSV (cm/s)	Plaque	ICA/CCA PSV ratio	ICA EDV (cm/s)
Normal	<125	None	<2	<40
<50%	<125	<50% diameter reduction	<2	<40
50%-69%	125-230	≥50% diameter reduction	2.0-4.0	40-100
70% to near occlusion	>230	≥50% diameter reduction	>4	>100
Near occlusion	High, low, or undetectable	Visible, detectable lumen	Variable	Variable
Occlusion	Undetectable	Visible, no detectable lumen	Not applicable	Not applicable

Abbreviations: CCA, common carotid artery; EDV, end-diastolic velocity; ICA, internal carotid artery; PSV, peak systolic velocity.
[a]Data from Grant EG, Benson CB, Moneta GL, et al. Carotid artery stenosis: gray-scale and Doppler US diagnosis—Society of Radiologists in Ultrasound Consensus Conference. *Radiology*. 2003;229(2):340-346.

FIGURE 24.2 Two color Doppler carotid artery studies, each showing different degree of the extracranial internal carotid stenosis. The studies show B-mode (brightness mode) ultrasound image (grayscale) of the internal carotid artery (ICA) with corresponding atherosclerotic plaque, C mode (color mode) with color-coded blood flow velocity in the chosen volume sample (*the selected box in the image*), and D mode (Doppler mode) with the blood flow waveforms representing the velocity profile calculated from the Doppler shift (waveforms shown with velocity in cm/s) in each picture from the chosen volume sample (represented by the *diagonal line* within the color-selected box). The peak systolic and end-diastolic velocities are marked with the *yellow calipers* in both pictures and used for the assessment of the degree of carotid stenosis. Two examples of varying degrees of ICA stenosis are presented. **A:** An ICA stenosis of 40% to 60%, with peak systolic velocity of 179.5 cm/s and end-diastolic velocity of 40.7 cm/s (or 50%-70% stenosis using the Society of Radiologists in Ultrasound Multidisciplinary Consensus Criteria LEVEL 1[1]). **B:** An ICA stenosis of 60% to 80% (or >70% using the Society of Radiologists in Ultrasound consensus), with peak systolic velocity of 434.4 cm/s and end-diastolic velocity of 144.8 cm/s and moderate turbulent blood flow.

FIGURE 24.3 Carotid in-stent stenosis. Color Doppler of the common carotid artery and the internal carotid artery shows stent placed in both arteries. The lumen in the proximal internal carotid artery is reduced. The peak systolic and end-diastolic velocities are marked with the *yellow calipers* in spectral image and used for the assessment of in-stent stenosis. In the narrowing segment, peak systolic velocity was 218.9 cm/s and end-diastolic velocity 51.1 cm/s, which indicates in-stent stenosis greater than 50%.

Carotid Ultrasound of Carotid Plaque Size, Morphology, and Carotid Intima-Media Thickness

Carotid ultrasound provides information on plaque size (regardless of the degree of stenosis) and plaque echomorphology and arterial wall thickness or carotid IMT (Fig. 24.4). The *presence of small nonstenotic carotid plaque* on ultrasound is an independent predictor of future stroke and other cardiovascular disease independent of the degree of stenosis, although it is related to the degree of carotid stenosis.

Detection of *plaque ulceration* by ultrasound imaging is limited except in contrast-enhanced carotid imaging, which is primarily limited to research settings. However, plaque *surface irregularity* is easy to detect on carotid ultrasound and was shown to be associated with an increased risk of stroke. Ultrasound may help characterize plaque using a qualitative scoring system (echolucent or echodense; homogenous or heterogeneous plaque) as well as by the quantitative, computer-assisted echodensity parameters such as the *grayscale median index* that was shown to be clinically relevant in the prediction of stroke. *Echolucent carotid plaque* (soft, with predominately lipid content) has been associated with an increased risk of first-ever stroke or myocardial infarction in asymptomatic individuals as well as with restenosis and more recurrent events after carotid stenting. *Echodense carotid plaque* (calcified) is in general considered to be of a good prognostic feature based on the lower rates of stroke. Recent studies,

FIGURE 24.4 Two color Doppler carotid artery studies, each showing B-mode (brightness mode) ultrasound image (grayscale). Figure on the **left** shows carotid intima-media thickness (IMT) automated measurements using edge-detection algorithm *(colored lines)* in the common carotid artery near wall (the mean IMT 0.756 mm, which is considered within normal range for adults). Figure on the **right** shows a large carotid plaque in the carotid bifurcation extending to the internal carotid artery that is measured by the automated edge-detection algorithm (plaque is outlined by the *colored line* and *green area* and measures 50.28 mm^2, indicating moderate to severe atherosclerosis).

however, have shown opposite results with an increased risk of stroke. Similar observation was reported for coronary calcium score. This presumably paradoxical effect of plaque calcification may be explained by the fact that echodense plaque is not a cause of stroke but rather a marker of presence of an "active" plaque in other vascular beds, which then can explain its association with increased vascular risk.

Carotid IMT is a measure of subclinical atherosclerosis shown to be associated with an increased risk of stroke and other cardiovascular disease. It has been used extensively as an outcome measure in numerous clinical trials testing the effect of lipid, blood pressure, and glucose-lowering medications. It has been associated with traditional vascular risk factors across different age groups, including in children and young adults. The American Society of Echocardiography and Society for Vascular Medicine have supported the use of carotid IMT in vascular risk stratification in moderate-risk individuals and outlined the recommendations for the IMT protocols LEVEL 2.[3]

Duplex Ultrasound of the Vertebral Arteries

The ultrasound evaluation of the VAs is similar to that of the carotid arteries. Examination of the VA is, however, limited by its anatomy because VA, unlike the carotid, cannot be traced continuously when it passes within the transverse processes of cervical vertebrae. Therefore, ultrasound examination of the extracranial VA is reliable only at the origin, intervertebral segments, and at the atlas loop portion. Color Doppler and power Doppler are particularly useful in assessing the caliber of VAs. Use of other diagnostic technologies (magnetic resonance angiography, CTA, and even conventional angiography) is often recommended in symptomatic patients with suspected VA stenosis on duplex ultrasound.

Multiparametric Extracranial Ultrasound

Newer techniques like contrast-enhanced ultrasound, tissue elastography, and three-dimensional (3D) ultrasound have been recently introduced as multiparametric ultrasound technologies for research. These novel technologies have expanded the fundamental role of ultrasound in clinical assessments as well but only in advanced laboratories. Contrast-enhanced ultrasound vascular imaging uses intravenous ultrasound contrast agents (gas-filled microbubbles), which serve as intravascular reflectors of ultrasound waves. The potential clinical use of contrast-enhanced ultrasound has been proposed in different vascular beds including the carotid arteries. It is particularly useful in the situations of poor visualization of high-grade carotid stenosis or suspected occlusion, complex carotid plaque imaging, and evaluation of plaques with suspected ulcerations. It also provides a noninvasive method for the assessment of the vasa vasorum and the vascularization of the atherosclerotic plaque neovascularization, possibly helping in the risk stratification of patients with high risk of plaque rupture. The use of targeted microbubbles further enhances the diagnostic capabilities of vascular ultrasound by detecting specific molecular processes important in the pathophysiology of atherosclerosis. Similarly, tissue-elastography and 3D carotid ultrasonography detect vulnerable carotid plaque (plaques prone for rupture and embolization) with more precision. The current ultrasound systems are equipped with these novel ultrasound imaging modalities, and their research advances may be soon incorporated into clinical practice. However, these techniques are currently not optimized for clinical use as there are no standards for performing and evaluating the results obtained by these new technologies. Although the adoption of multiparametric ultrasound into clinical practice could help in better prediction of stroke risk, it is not routinely used in clinical practice.

Indications for Extracranial Ultrasound Examination

The guidelines for noninvasive vascular testing and indications for vascular ultrasound has been proposed by the American Society of Echocardiography and the Society for Vascular Medicine and adopted by other professional organizations, Centers

for Medicare & Medicaid Services, and private insurers LEVEL 3.[4] *Indications for carotid artery ultrasound* include the following:

- Evaluation of patients with cerebral ischemia, stroke, or transient ischemic attack
- New or worsening hemispheric neurologic symptoms (eg, unilateral motor or sensory deficit, speech impairment, or amaurosis fugax)
- Hollenhorst plaque visualized on retinal examination
- Evaluation of patients with a cervical bruit
- Evaluation of pulsatile mass in the neck
- Evaluation of blunt neck trauma
- Preoperative evaluation of patients undergoing major cardiovascular or other major surgical procedures, including cardiac, liver, and kidney transplant
- Drop attacks or syncope (rare indications primarily seen in vertebrobasilar insufficiency or bilateral carotid artery disease)
- Syncope of uncertain cause after initial cardiovascular evaluation
- Light-headedness or impaired vision in the setting of upper extremity exertion
- Suspected symptomatic vertebrobasilar occlusive disease in the symptomatic patient (eg, vertigo, ataxia, diplopia, dysphagia, dysarthria)
- Vasculitis involving extracranial arteries
- Follow-up of patients with known carotid artery disease
- Evaluation of postoperative patients following carotid endarterectomy or carotid stenting (surveillance after carotid artery intervention)
- Evaluation of suspected subclavian-vertebral steal phenomenon
- Evaluation of suspected carotid or VA dissection

INTRACRANIAL ULTRASOUND (TRANSCRANIAL DOPPLER)

Transcranial Doppler (TCD) is a noninvasive ultrasound technology that provides real-time information on blood flow velocity and blood flow direction in large intracranial arteries. Using a probe with great tissue-penetration properties, it is possible to insonate the major vessels of the circle of Willis, the distal intracranial segments of the VAs, and much of the length of the basilar artery (BA). Most TCD devices have a color-coded B mode and power Doppler display. The TCD provides only spectrum analysis of blood flow velocities, whereas transcranial color duplex imaging provides spectrum analysis as well as color-coded imaging of the intracranial vessels and visualization in power Doppler. Transcranial power motion Doppler is the technology that continuously displays flow intensity and direction of blood flow over 6 cm of intracranial space. Its advantage is in easier insonation, which allows inexperienced individuals to learn technique faster. Any of these TCD technologies produce the spectral signal that estimates of the cerebral hemodynamic status and the degree of arterial stenosis.

Arteries of the circle of Willis are insonated through temporal, orbital, suboccipital (foramen magnum), and submandibular acoustic "windows." In about 10% to 20% of individuals, the intracranial arteries cannot be assessed due to poor acoustic windows due to thick bones. This is particularly the case in elderly and postmenopausal women. The measures used include distance from the probe, direction of flow (toward or away from the probe), flow velocities, waveform characteristics

$$\text{Pulsatility Index (PI)} = \frac{PSV - EDV}{MV}$$

$$\text{Resistance Index (RI)} = \frac{PSV - EDV}{PSV}$$

FIGURE 24.5 A sample of normal waveform in the middle cerebral artery with the algorithms for calculation of pulsatility index and resistance index. Abbreviations: EDV, end-diastolic velocity; MV, mean velocity; PSV, peak systolic velocity.

(low-resistance and high-resistance pulsatile waveform), and derived blood flow indices including pulsatility index and resistance index (Fig. 24.5).

Indications for Transcranial Doppler Ultrasound

The American Institute of Ultrasound in Medicine has published practice guidelines LEVEL 3,[5] for the performance of TCD for adults and children. The *TCD indications in adults* include the following:

- Detection and follow-up of stenosis or occlusion in a major intracranial artery in the circle of Willis and vertebrobasilar system and monitoring of thrombolytic therapy in acute stroke
- Detection of cerebral vasculopathy
- Detection and monitoring of vasospasm in patients with subarachnoid hemorrhage
- Evaluation of collateral pathways of intracranial blood flow, including after intervention
- Detection of circulating cerebral microemboli
- Detection of right-to-left shunts
- Assessment of cerebral vasomotor reactivity (CVR)
- As an adjunct in the confirmation of the clinical diagnosis of brain death
- Intraoperative and periprocedural monitoring to detect cerebral embolization, thrombosis, hypoperfusion, and hyperperfusion
- Evaluation of sickle cell disease to determine the stroke risk
- Assessment of arteriovenous malformations (AVMs)
- Detection and follow-up of intracranial aneurysms
- Evaluation of positional vertigo or syncope

Additional *TCD applications in children* include the following:

- Assessment of intracranial pressure and hydrocephalus
- Assessment of hypoxic ischemic encephalopathy
- Assessment of dural venous sinus patency

In the American Academy of Neurology report LEVEL 1,[6] the highest level of evidence was given to the use of TCD for the screening of children aged 2 to 16 years with sickle cell disease for stroke risk (type A, class I) and the detection and monitoring of angiographic vasospasm after spontaneous subarachnoid hemorrhage (type A, class I-II) (Table 24.3).

TABLE 24.3 Recommendations and Level of Evidence for the Use of Transcranial Doppler by the American Academy of Neurology Therapeutics and Technology Assessment Subcommittee[a,b]

Setting/Disease/Condition	Rating of Recommendation/Level of Evidence
Sickle cell disease	Type A, class I
Detection and monitoring of angiographic vasospasm	Type A, class I-II
Detection of cerebral circulatory arrest/brain death	Type A, class II
Intracranial steno-occlusive disease	Type B, class II-III
Vasomotor reactivity testing	Type B, class II-III
Monitoring carotid endarterectomy	Type B, class II-III
Cerebral microembolism detection	Type B, class II-IV
Monitoring cerebral thrombolysis	Type B, class II-III
Monitoring coronary artery bypass graft surgeries	Type B-C, class II-III
Right-to-left cardiac shunts	Type A, class II
Intracranial occlusive disease	Type B, class II-IV

[a]Type A, established as useful/predictive recommendation; type B, probably useful/predictive; type C, possibly useful/predictive; class I, evidence provided by prospective study in broad spectrum of persons with suspected condition, using a "gold standard" to define cases, where test is applied in blinded evaluation, and enabling assessment of appropriate tests of diagnostic accuracy; class II, evidence provided by prospective study in narrow spectrum of persons with suspected condition or well-designed retrospective study of broad spectrum of persons with suspected condition (by gold standard) compared with broad spectrum of controls where test is applied in blinded evaluation and enabling assessment of appropriate tests of diagnostic accuracy; class III, evidence provided by retrospective study where either persons with established condition or controls are of narrow spectrum and where test is applied in blinded evaluation; class IV, any design where test is not applied in blinded fashion or evidence provided by expert opinion or descriptive case series.

Sickle Cell Disease

The TCD is an important tool for the selection of children with sickle cell disease in need of blood transfusion and who should stay on blood transfusion to sustain the benefit for prevention of stroke. In the Stroke Prevention Trial in Sickle Cell Anemia, TCD detection of time-averaged maximum mean flow velocity (MFV) of 200 cm/s on two separate examinations in middle cerebral artery (MCA) or terminal ICA was used to determine the need for blood transfusion that resulted in 90% relative risk reduction of first-ever stroke. Moreover, long-term follow-up results from the Stroke Prevention Trial in Sickle Cell Anemia indicated that persistent elevation in TCD velocities in these patients is indicative of ongoing increased risk of stroke.

Intracranial Stenosis and Occlusion

Stenosis of greater than 50% lumen narrowing can reliably be detected by TCD in arterial segments with anatomically favorable insonation angles, particularly in the M1 segment of the MCA. Significant narrowing of intracranial arteries results in focal increases in flow velocities, turbulent flow, and increased waveform pulsatility at the level of stenosis. Compensatory collateral flow from uncompromised vessels to deprived areas may result in flow reversal and augmentation of flow. Because some patients have suboptimal temporal windows, failure to obtain a waveform reading does not imply vessel occlusion unless a prior study had demonstrated vessel patency. An intracranial stenosis of the major intracranial arteries should be suspected when the normal hierarchy of the flow velocities is disrupted. The flow in the MCA should be greater than in the anterior cerebral artery, where blood flow velocities should be greater than in the posterior cerebral artery or BA and VA. The difference in these disrupted MFV should be greater than 20%. According to the Stroke Outcomes and Neuroimaging of Intracranial Atherosclerosis criteria LEVEL 3,[7] the TCD MFV cutoff for more than 50% stenosis for MCA is greater than 100 cm/s and for VA and BA is greater than 80 cm/s (**Fig. 24.6**).

Sensitivity and Specificity of Transcranial Doppler in Detecting Intracranial Stenosis

The TCD can reliably detect stenosis in M1 segment of MCA, ICA syphon and terminal ICA, terminal VA, proximal BA, and P1 segment of posterior cerebral artery. The sensitivity of TCD for stenosis in these segments is 85% to 90%, and specificity is 90% to 95%. The PPV is 85% and negative predictive value is 98%, with lower accuracy values for posterior circulation. In the Stroke Outcomes and Neuroimaging of Intracranial Atherosclerosis trial LEVEL 3,[7] the accuracy of TCD in detection of intracranial steno-occlusive disease was superior to CTA or digital subtraction angiography for ruling out than ruling in stenosis (having a higher negative predictive value than PPV) for all intracranial arterial segments.

Detection of Arteriovenous Malformations

The AVMs are direct communications between the arterial and venous systems, without an intervening capillary bed. No resistance vessels exist to impede or regulate flow, and therefore, flow measurements from feeding vessels typically demonstrate elevated velocities and low-resistance waveforms. Because of the large volume of flow that traverses an AVM, flow patterns may also be altered in vessels not directly connected to the AVM, resulting in altered waveform recordings. The TCD is sensitive for the detection of medium- to large-sized AVMs. Transcranial color duplex imaging may be very useful in evaluation of AVMs

FIGURE 24.6 Example of transcranial Doppler study of the both middle cerebral arteries (MCA) in patients with left MCA stenosis. The spectral velocities are obtained at the depth of 50 cm from both sides of the head overlying the temporal bone. The blood flow velocity profile of the Doppler shift is calculated from the blood in the MCA flowing toward the probe (*the red arrow on the left side of both images directed toward the probe*). The image on the left **(A)** represents the normal spectral flow with peak systolic velocity of 184 cm/s and end-diastolic velocity of about 80 cm/s in a young individual. The image on the right **(B)** represents the high-grade MCA stenosis with systolic blood flow velocity over 333 cm/s and end-diastolic blood flow velocity of 231 cm/s and marked turbulent flow.

as it may provide more information about anatomic characteristics of AVMs than regular TCD.

Vasospasm in Subarachnoid Hemorrhage

The TCD has become a standard procedure for the detection, quantification, and monitoring of arterial vasospasm after subarachnoid hemorrhage or head trauma. Most clinically important spasm occurs in the proximal cerebral vessels, which are accessible to TCD insonation. The TCD monitoring, however, is limited in identifying vasospasm in distal cerebral arteries. The TCD flow velocity criteria appear to be most reliable for detecting angiographic MCA and BA vasospasm. Mean MCA velocities greater than 120 cm/s are indicative of moderate vasospasm, whereas velocities greater than 200 cm/s show severe vasospasm. A Lindegaard ratio (MFV MCA/ICA) greater than 3 is suggestive of vasospasm, whereas a ratio of 6 or greater reliably predicts the presence of clinically significant angiographic vasospasm. In addition, a sudden rise in MCA MFV by greater than 65 cm/s or by 20% increase is suggestive of vasospasm. The TCD is most useful in monitoring the temporal course of vasospasm to help guide the timing of additional diagnostic procedures and therapeutic angiographic interventions.

Cerebral Microemboli Detection

The TCD can detect microemboli or high-intensity transient signal in real time. Cerebral microemboli account for up to 70% of all ischemic strokes. Most of cerebral emboli originate from carotid atherosclerosis and cardiac sources including atrial fibrillation, prosthetic heart valves, right-to-left cardiac shunt (patent foramen ovale), aortic arch atheroma, vertebral disease, and stenosis in other intracranial arteries. Criteria for microemboli are established by the consensus committee at the Ninth International Cerebral Hemodynamic Symposium LEVEL 3,[8] which defines microembolus as a TCD signal with (1) random occurrence during the cardiac cycle, (2) brief duration (embolic signals should be transient lasting <300 ms), (3) high intensity (at least 3 dB higher than the background blood flow signal), (4) primarily unidirectional signal within the Doppler spectrum, and is (5) accompanied by an audible component ("snap," "chirp," or "pop").

Cerebral Vasomotor Reactivity Testing

The TCD can be used to assess cerebral hemodynamic reserve. When arterial perfusion is compromised, distal regulating arterioles dilate to allow more flow and to prevent cerebral ischemia. However, when perfusion is severely impaired, the arterioles are maximally dilated and CVR decreases or disappears, indicating a state of exhausted cerebrovascular reserve or "misery" perfusion. Impaired CVR may predict impending ischemia in patients with extracranial or intracranial artery stenosis or occlusion. The CVR testing include the breath holding index, blood pressure changes, or the carbon dioxide inhalation test. Impaired CVR has been found in various conditions, including severe carotid artery stenosis, stroke, sleep apnea, and congestive heart failure. The CVR is not a direct measure of cerebral autoregulation, but newer methods that include correlations between flow velocities and spontaneous fluctuations in blood pressure have been developed to assess cerebral autoregulation (dynamic cerebral autoregulation [dCA]). The TCD in combination with continuous blood pressure measurement is a technology that offers evaluation of cerebral autoregulation that is particularly

impaired in patients with stroke. However, there are no standards for TCD-dCA methodology, and therefore, the use of TCD-dCA is currently not used in clinical practice.

Sonothrombolysis

The TCD may be hold some promise in care as an adjunct therapy to intravenous thrombolysis after acute MCA occlusion. However, it is still under research and not yet used in clinical practice. Application of *intravascular low-intensity ultrasound* at the site of occlusion may enhance the outcome after ischemic stroke even without the administration of tissue plasminogen activator (tPA). Also, augmentation of tPA-associated thrombolysis with standard diagnostic TCD monitoring has been safe and associated with a higher arterial recanalization rate. Cochrane Stroke Group reported that sonothrombolysis was likely to reduce death or dependency and patients who received any form of sonothrombolysis had more than twofold higher likelihood of achieving complete arterial recanalization than thrombolysis alone. In addition, gaseous microspheres, initially developed as ultrasound contrast agents, can further increase the effectiveness of tPA. A microsphere dose-escalation study showed sustained complete recanalization rates of 67% in patients receiving TCD monitoring with perflutren lipid microspheres compared to controls receiving tPA alone with no increase in hemorrhage rate. Sonothrombolysis using TCD with the administration of microspheres may further improve thrombolytic effect in acute stroke management in the future.

Limitations of Transcranial Doppler

The TCD is highly operator dependent. It requires technical skills, detailed 3D knowledge of cerebrovascular anatomy and its variations, and global understanding of brain hemodynamics. The use of TCD is also limited by the 10% to 20% rate of inability to perform TCD due to inadequate acoustic windows, which is prevalent in elderly. This is related to thickness and porosity of the bone, which causes attenuation of the ultrasound energy transmission. The TCD examination is also limited to the large cerebral basal arteries, and it cannot directly examine a status of local cerebral blood flow. The proper performance of TCD and interpretation of TCD finding require specialized training and hands-on skills, which is not often available during traditional medical training. These limitations of TCD are the main reason for its underutilization, and most of them can be overcome by vascular laboratory accreditation and proper training and certification of sonographers and interpreting physicians.

SUMMARY

Extracranial and transcranial Doppler are clinically established noninvasive imaging neuroimaging modalities. Their value, however, has been constantly assessed and their validity evaluated. As new neurovascular laboratories are established, it is important that these new laboratories establish their normative values using guidelines provided in this brief neurosonology fundamentals and other established guidelines in the literature. These imaging modalities are now integral part of most stroke units. However, they are still infrequent in community hospitals and outpatient settings and therefore less accessible outside larger medical centers.

25 Angiography and Neuroendovascular Surgery

Katarina Dakay, Scott M. Woolf, Gurmeen Kaur, Daniel H. Sahlein, and Fawaz Al-Mufti

KEY POINTS

1. Neuroendovascular surgery allows for diagnosis and treatment of cerebral aneurysms, arteriovenous malformations, acute ischemic stroke with large vessel occlusion, atherosclerotic lesions, and venous abnormalities.
2. The most common complication of diagnostic cerebral angiogram is access site hematoma.
3. Several randomized controlled trials have demonstrated the benefit of mechanical thrombectomy in patients with acute ischemic stroke caused by large vessel occlusion who meet certain clinical and imaging criteria.
4. Current techniques for endovascular treatment of acute ischemic stroke with large vessel occlusion include mechanical thrombectomy, direct clot aspiration, intra-arterial lytics, and combination methods.
5. Strategies for endovascular treatment of cerebral aneurysms include coiling, stent-assisted coiling, flow-diverting stents, neck reconstruction device plus coiling, and more recently the intrasaccular Woven EndoBridge device.
6. Areas of active research and development in the neurointerventional field include the use of intracranial stenting for intracranial atherosclerosis, venous sinus stenting for idiopathic intracranial hypertension, middle meningeal artery embolization for chronic subdural hematoma, neuroendovascular delivery of chemotherapeutic agents, and expanding the indications for mechanical thrombectomy, among others.

INTRODUCTION

Neuroendovascular surgery (NES) is a subspecialty that uses endovascular access, most often peripheral, to gain entry to the vasculature of the brain and spinal cord in order to visualize and treat a wide array of neurologic conditions. Neuroendovascular surgeons diagnose and manage many different disease processes, including acute ischemic stroke, carotid artery stenosis, cerebral aneurysms, and arteriovenous malformations (AVMs), among others.

The foundation of NES is cerebral angiography, which can be used as a purely diagnostic test or as a means of access for an interventional procedure. Significant advantages of neurointerventional procedures are their minimally invasive nature compared to open surgery, the ability to navigate deep structures, which would be challenging or impossible to safely access with conventional surgical techniques, and the utility of angiography to simultaneously visualize and treat lesions with exquisite detail.

NES is a subspecialty that comprises aspects of neurosurgery, radiology, and neurology; it is also sometimes referred to as *endovascular surgical neuroradiology*, *interventional neurology*, or *endovascular neurosurgery*. These multiple terms illustrate the unique diversity of the neurointerventional workforce, a specialty in which neurosurgeons, neurologists, and radiologists are eligible for training. The unique perspectives brought by each field have ushered the subspecialty into an era of rapid growth and expansion, as neurointerventional devices continue to improve and evolve, and conditions such as basilar tip aneurysms previously thought to be inaccessible for treatment are now able to be secured. Although the first diagnostic angiography was performed nearly a century ago, it is primarily within the last two decades that technologic advances and new research have allowed NES to expand into its current state as a major diagnostic and therapeutic technique. This chapter discusses the history of neurointervention, important procedural considerations and complications, conditions in which neuroendovascular treatment is used, and, finally, areas of active research and development within the neurointerventional field.

HISTORY

The first diagnostic cerebral angiogram performed on a living patient was by Portuguese neurologist Egaz Moniz in 1927; Moniz had previously experimented with injecting contrast into cadavers and dogs. Prior to the successful angiogram in 1927, Moniz had previously attempted angiography with a more potent contrast medium, 70% strontium bromide, which caused a transient Horner syndrome in two patients and death of one patient due to stroke. It was because of this that Moniz temporarily abandoned the procedure before adapting his technique to use 25% sodium iodide. Later, Thorotrast, a thorium dioxide–based contrast media, was used; however, it was abandoned after it was found to have a high incidence of delayed carcinogenesis. Over the subsequent decades, the contrast solutions were refined, increasing the safety of neuroangiographic procedures; a shift from high-osmolality, ionic contrast media such as meglumine to lower risk, low-osmolality nonionic media such as iohexol (Omnipaque) has improved the tolerability and safety of contrast administration.

In the early era of angiography, procedures were performed with direct carotid puncture, a method which had a high risk of complications. In the 1940s, physicians began to use peripheral access in order to gain access to the intracranial vessels. The first angiography of the aorta by femoral access was performed by Farinas in 1941, and in fact, the first radial angiography in which the vertebral artery was examined was performed in 1947

by Radner. In the 1960s, femoral access for carotid and vertebral angiography became commonplace. Prior to the era of computerized tomography, one of the major indications for cerebral angiography was to visualize tumors, in which the location of the tumor could be surmised by visualizing which vessels were displaced and in which direction. Initially, only extracranial arteries were accessible; however, in the 1960s, the first experimental usage of flexible catheters to enter the intracranial circulation was reported. In the 1970s, Serbinenko developed a nondetachable balloon used to obliterate carotid-cavernous fistulae; it was also during this decade that the liquid embolic agent cyanoacrylate was developed by Zanetti and Sherman.

In 1991, neuroendovascular therapy underwent a significant breakthrough with the invention of Guglielmi detachable coils, a platinum-based electrolytically detachable coil, which could be deployed into a cerebral aneurysm, causing thrombosis within the aneurysm dome due to interaction between the positively charged coil and negatively charged fibrinogen, leukocytes, erythrocytes, and platelets. During the 1990s, coil technology continued to be refined with three-dimensional coils and coils formed with a bioactive coating. In the late 1990s, endovascular therapy for acute stroke treatment also began with the study of intra-arterial urokinase in the Prolyse in Acute Cerebral Thromboembolism (PROACT)-I and PROACT-II trials, which showed the potential for benefit of endovascular therapy in acute ischemic stroke; however, these trials were followed by negative trials such as the Randomized Controlled Trial on Intra-arterial Versus Intravenous Thrombolysis in Acute Ischemic Stroke (SYNTHESIS) and Mechanical Retrieval and Recanalization of Stroke Clots using Embolectomy (MR-RESCUE) trials. These negative results dampened enthusiasm for endovascular stroke treatment until 2014, when several randomized controlled trials demonstrated the benefit of mechanical thrombectomy in carefully selected patients with anterior circulation large vessel occlusion.

In the early 2000s, flow diversion with an endoluminal stent, the Pipeline Embolization Device, was developed for treatment of aneurysms with features that rendered them untreatable by coiling. Further developments during this timeframe included the refinement of stent retrievers for mechanical thrombectomy, the increasing utilization of perfusion-based imaging for patient selection in stroke care, and the development of new liquid embolic agents, such as *n*-butyl cyanoacrylate ("glue") and Onyx.

The neurointerventional field continues to evolve and expand; topics of ongoing active research and development are described at the conclusion of the chapter.

PROCEDURAL OUTLINE AND CONSIDERATIONS

Preprocedural Considerations

Preprocedural considerations include those applicable to any preoperative evaluation and those specific to the neuroendovascular realm. The indication for the study should be assessed; common indications for angiography include the evaluation and treatment of a known or suspected cerebral aneurysm or AVM, evaluation or treatment of extracranial or intracranial stenosis, emergent treatment of acute ischemic stroke caused by large vessel occlusion, and arteriovenous fistulas. Less commonly encountered but significant other conditions in which angiography is often employed include evaluation of moyamoya disease, fibromuscular dysplasia, suspected central nervous system vasculitis, and reversible cerebral vasoconstriction syndrome. Noninvasive alternatives to angiography should be considered, particularly in cases where angiography is being employed strictly as a diagnostic tool; for example, recent literature suggests that the diagnosis of reversible cerebral vasoconstriction syndrome can often be made based on clinical features and noninvasive vessel imaging.

A thorough history and physical should be obtained from the patient, with careful attention to the neurologic examination to identify any baseline neurologic abnormalities. Additionally, assessment of the Mallampati scale and palpation of distal pulses is important in the preoperative patient.

It is paramount to review any prior angiographic studies because findings such as carotid stenosis or a heavily calcified aortic arch have implications on the risk of catheterization and may guide either alternate diagnostic modalities or the placement of the catheter. Likewise, any available noninvasive imaging of the aortic arch or cerebral vasculature of interest, such as computed tomography or magnetic resonance angiogram, should be reviewed. Allergies, particularly to antiplatelets, heparin, or contrast media, should be meticulously noted. Clinicians should be aware of any prior adverse reactions to anesthesia in the past as well as any concomitant medical conditions such as obstructive sleep apnea and renal or hepatic insufficiency that may contribute to an increased risk of anesthetic complications. Any history of groin complications should be considered seriously because this may influence decision to either use the contralateral side or a different vessel. Clinicians should note the patient's medication list, with careful attention to antiplatelet or anticoagulant regimen, as well as metformin, which is often held in the perioperative period because of the risk of lactic acidosis should contrast nephropathy develop.

Procedure

Cerebral angiography is performed by obtaining peripheral access, typically femoral or radial, and using a guidewire inserted within a hollow catheter to engage the aortic arch and then select the precerebral and cerebral vessels. Figure 25.1 demonstrates the basic equipment required to perform an angiogram. Although the femoral artery has traditionally been the site of access, recent studies show that the radial artery can be cannulated with a high success rate of up to 99.3% in experienced operators with no major complications in one case series, and randomized controlled trial data extrapolated from coronary angiography suggests that radial access is associated with reduced all-cause mortality and groin access complications LEVEL 1.[1] This has resulted in the European Society of Cardiology recommending radial access site as the preferred access site for patients with non-ST segment myocardial infarction undergoing invasive revascularization. Advantages over radial access include patient's preference, a shorter observation period for outpatient procedures, and the ability to sit up immediately after the procedure. Challenges of radial access include a learning curve prior to acclimation in clinicians new to the technique, the current limitations in adapting catheter equipment designed for the femoral artery to radial access particularly in interventional cases, and radial artery vasospasm; however, intra-arterial spasm can be treated with an antispasmodic cocktail of verapamil and nitroglycerin.

Angiography can be performed in the awake patient with conscious sedation or under generalized endotracheal anesthesia, depending on the patient's preferences and cooperation, the

FIGURE 25.1 Basic equipment required for a diagnostic angiogram including heparinized saline flush lines, syringes for contrast and saline hand injection, micropuncture kit, sterile drape, sterile gauze, and bowls to hydrate the hydrophilic guidewires while not in use.

procedure being performed, and the potential need for neuromuscular paralysis for particular interventions in which even small movements could be treacherous. Although the particular technical nuances of each neurointerventional procedure are beyond the scope of this chapter, the general steps involved in a diagnostic cerebral angiogram are explained in the following text.

First, the patient is positioned on the angiography table; the method of access is determined and either the femoral or radial artery should be palpated and identified. The area is then sterilized with chlorhexidine or a similar agent, and a sterile drape is placed over the patient. The head should be secured, often with a headrest and/or tape. Either anatomic landmarks, fluoroscopy, sonographic guidance, or a combination of these methods is used to verify the access site. Topical anesthesia with lidocaine is employed in the consciously sedated patient. Sonographic guidance allows the examiner to directly visualize the artery being cannulated; one meta-analysis showed that the use of ultrasound guidance for percutaneous coronary intervention decreased the rate of inadvertent venipuncture and bleeding events.

Once the puncture needle has been inserted and there is blood return, an introducer wire is placed through the needle and advanced into the vessel; this is done under fluoroscopic guidance to confirm that the puncture is arterial. The needle is removed and a dilator is inserted over the wire and then replaced with an introducer sheath, which is then connected to a continuous heparinized saline flush. Intravenous heparin is often given during the procedure, with monitoring of activated clotting time levels being crucial particularly with longer procedural times such as interventional cases.

The diagnostic catheter, preflushed with heparinized saline and with a guidewire inserted, is then inserted into the sheath and advanced under fluoroscopic guidance into the thoracic aorta. The wire is then removed, and the catheter is flushed with heparinized saline to remove any bubbles, clots, or debris. The catheter is then placed on either continuous saline flush or maintained on a meticulous hand-flush regimen for the duration of the study. The guidewire is replaced into the catheter, and the operator leads with the wire in order to traverse the great vessels and select the appropriate vessel for study; contrast is "puffed" into the catheter to visualize the outline of the vessel. Imaging techniques such as "roadmapping" allow for the superimposition of a live fluoroscopic image onto a stored subtraction image to assist the operator in confirming catheter location. The biplane is then adjusted to obtain standardized views of the vessels being catheterized; contrast is injected through the catheter as images are captured. Figure 25.2 demonstrates standard anteroposterior and lateral views of the right internal carotid artery, and Figure 25.3 demonstrates standard views of the vertebral artery. In particular conditions such as aneurysm or AVMs, three-dimensional spin imaging is employed using a power injector to inject contrast through the catheter parked in the vessel of interest, as the C-arm of the biplane rotates around the patient's head, capturing a series of images that are then compiled into a three-dimensional reconstruction.

Once all necessary images have been captured, the catheter is pulled back under fluoroscopic guidance; in most cases, a femoral arteriogram is captured to evaluate the placement of the sheath. The decision of whether to hold pressure or place a closure device is then made; either a wire is inserted to exchange the sheath for a closure device or the sheath is simply removed under manual pressure, which is held for a variable period of time depending on the size of the catheter and patient-specific characteristics such as anticoagulation use. Both femoral and dorsalis pedis pulses are palpated and monitored both immediately and for several hours after the study. A sterile dressing should be placed over the puncture site once hemostasis is confirmed.

Postprocedural Care

Meticulous attention should be paid to the access site and distal pulses; the extremity in which arterial access was obtained should be immobilized for a period of several hours depending on the size of the sheath and the method of closure. Blood pressure parameters

FIGURE 25.2 Anteroposterior **(left)** and lateral **(right)** views of a normal right internal carotid angiogram showing the internal carotid artery *(dotted arrows)*, middle cerebral artery *(white arrows)*, and anterior cerebral artery *(black arrows)*.

should be stipulated particularly in cases where interventions were performed; an arterial line for continuous blood pressure measurements may be necessary in some cases. Neurologic status should be monitored, and any changes in the neurologic exam should prompt consideration of appropriate neuroimaging. Appropriate antiplatelet regimen should be maintained in cases in which an intravascular stent was placed. It is crucial that the clinician be aware of both general angiographic complications and procedure- and condition-specific considerations; procedure-specific complications are outlined in the sections to follow.

COMPLICATIONS OF ANGIOGRAPHY

Complications of angiography include access site complications, perioperative stroke or transient ischemic attack, and complications related to contrast such as allergy or contrast-induced nephropathy (CIN). A retrospective study of over 19,000 diagnostic cerebral angiograms found that access site hematoma was the most common overall complication, occurring in 4.2% of patients; the rate of neurologic complications was 2.6%, and the rate of permanent neurologic disability from perioperative stroke was 0.14%.

Access Site Complications

Potential groin site complications include femoral artery dissection from subintimal passage of guidewire or malpositioned closure device; retroperitoneal hematoma from suprainguinal puncture; arterial pseudoaneurysm; and, rarely, acute lower extremity limb ischemia from arterial spasm, dissection, embolization of atherosclerotic plaque, or closure device. Retroperitoneal hematoma can cause hemodynamic instability; monitoring of vitals, hemoglobin and hematocrit, and visible hematoma expansion should be performed. Repletion of blood products may be necessary, and a type and screen and large-bore intravenous access are crucial; small hematomas may be treated conservatively, whereas larger hematomas often require surgical evacuation. Lower limb ischemia should warrant an emergent vascular surgery consultation, with consideration of anticoagulation and evaluation for emergent revascularization.

Contrast Allergy

Contrast allergy is seen in a minority of patients; if angiography is required, patients with a contrast allergy can be premedicated with a combination of antihistamines and steroids; if an acute

FIGURE 25.3 Anteroposterior **(left)** and lateral **(right)** views of a normal right vertebral artery angiogram demonstrating distal vertebral artery *(black solid arrows)*, posterior inferior cerebellar artery *(white solid arrows)*, anterior inferior cerebellar artery *(gray arrows)*, superior cerebellar artery *(white dotted arrows)*, and posterior cerebral artery *(black dotted arrows)*.

anaphylactoid reaction occurs with contrast exposure, administration of epinephrine is recommended. The American College of Radiology has outlined commonly encountered contrast reactions and proposed treatment algorithms.

Contrast-Induced Nephropathy

The rate of CIN from catheter-based angiography ranges from 0.5% to 6.0% in the published literature depending on the patient population and the definition of CIN employed; risk factors for CIN include preexisting diabetes mellitus and advanced age. Strategies recommended to reduce the risk of CIN include pre- and postoperative hydration, holding blood pressure medications and avoiding perioperative hypotension, and limiting contrast administration to the minimum necessary to obtain the required angiographic runs.

Neurologic Complications

Neurologic complications are the most feared consequence of diagnostic cerebral angiography; however, fortunately with the advent of technologic advances, the reported complication rate is as low as 0% to 2.3% for reversible neurologic deficits and 0% to 5% for permanent neurologic deficits. Older age and preexisting cardiovascular disease have been identified as risk factors for neurologic complications. However, these rates are reported for diagnostic angiograms only; the rate of complications with interventional procedures varies based on the clinical condition and technique being employed.

SELECTED CONDITIONS DIAGNOSED AND TREATED WITH NEUROINTERVENTIONAL PROCEDURES

Cerebral Aneurysms

Diagnosis and management of cerebral aneurysms is a common indication for endovascular treatment. Broadly, aneurysms can be categorized on their ultrastructural features such as their size, morphology, and location; however, the most significant distinction is between unruptured aneurysms and those which have ruptured and caused subarachnoid hemorrhage (SAH); both clinical scenarios are discussed in brief in the following text.

Unruptured Aneurysms

Unruptured aneurysms are present in approximately 3.4% of the population; often, these are discovered incidentally on neuroimaging performed for other indications. Risk factors for having a

cerebral aneurysm include family history of aneurysm in two or more first-degree relatives, smoking, hypertension, increasing age, and presence of certain disorders such as polycystic kidney disease or collagen vascular diseases. The International Study of Unruptured Intracranial Aneurysms was a large prospective study of patients with unruptured aneurysms dichotomized into two groups: those with a prior history of SAH from a separate aneurysm and those with no history of SAH; in patients with no history of SAH, the rupture rate for small aneurysms less than 10 mm in diameter was 0.05% per year. Factors associated with rupture risk in the group without prior history of SAH included posterior circulation or posterior communicating artery location and size; in the patients with a history of SAH, the rupture risk was 0.5% per year, 11 times higher than in the first group. Several risk scores have been proposed to assess the risk of SAH in unruptured intracranial aneurysms; these include the Population, Hypertension, Age, Size, Earlier subarachnoid hemorrhage, Site (PHASES) score, which is a composite of several of the risk factors noted earlier, and the Unruptured Intracranial Aneurysm score, which is based on location, size, current smoking, and age at diagnosis. A common challenge faced by neurointerventionalists is whether to treat these incidentally discovered aneurysms. The decision on whether to treat or observe unruptured intracranial aneurysms, and how often to follow with serial imaging, is at this time based on observational studies, patient's preference, and clinician's assessment of aneurysm- and patient-specific risk factors.

Surgical Versus Endovascular Treatment

The two major strategies for aneurysm treatment are surgical clipping and endovascular treatment; the latter is colloquially often referred to in the literature as *coiling*, although it is noteworthy that there are now several endovascular treatment strategies beyond coiling. Each treatment modality has its advantages. Endovascular treatment has been shown to be associated with a lower procedure-related morbidity and mortality but a higher rate of recurrence than surgical clipping.

The International Subarachnoid Aneurysm Trial was a prospective, randomized, multicenter trial of 2,143 patients comparing the safety and efficacy of endovascular coiling versus microsurgical clipping for ruptured cerebral aneurysms and found that for small- to moderate-sized anterior circulation aneurysms, there was a lower rate of death or dependency in the coiling group (24%) versus the clipping group (31%) LEVEL 1.[2,3] The Barrow Ruptured Aneurysm Trial showed similar findings in a smaller cohort of 471 patients; 34% of patients in the clipping arm versus 23% in the coil arm experienced death or dependency. The main disadvantage of the endovascular arm was that 33% of patients crossed over to surgical treatment LEVEL 1.[4]

Currently, the American Heart Association does not categorically recommend one treatment over the other but states that both clipping and coiling should be performed at high-volume centers accustomed to such treatment.

Overview of Endovascular Treatment Strategies for Aneurysms

Many endovascular strategies exist for treating aneurysms; most have only risen to prominence within the last decade. Each method has its own advantages and downsides; in some cases, aneurysm morphology may not allow for coiling but may be favorable for flow diversion. Aneurysm size, neck-to-dome ratio and other morphologic features, location, and proximity to other vessels all factor into the neurointerventionalist's decision on how to best secure an aneurysm.

Coiling

Although attempts at coiling aneurysms began several decades ago, coiling in earnest began in 1991 when Guido Guglielmi collaborated with the University of California Los Angeles to invent the prototypical coils used in practice today, termed *Guglielmi detachable coils*. These platinum-based detachable coils could be introduced through a catheter and then deployed into the aneurysm sac by electrolytic detachment; their positive charge attracts the negative charge of platelets, red blood cells, and white blood cells leading to thrombosis. The initial coil should provide a "frame" for additional coils; there are in fact framing coils designed precisely for this purpose. Subsequently, successive coils are deployed into the aneurysm until there is moderate resistance against further coil addition or until there is radiographic obliteration of the sac. Risks of coiling include aneurysm rupture, coil prolapse, and thrombosis of normal parent vessels.

Stent-Assisted Coiling and Balloon-Assisted Coiling

In some cases, aneurysm neck anatomy makes placement of coils challenging without prolapsing into the parent vessel. In these cases, an adjunctive technique with either a temporarily inflatable balloon or a permanent intravascular stent can help provide support and a scaffold on which coils can be placed in a satisfactory configuration. Balloon-assisted coiling involves temporary inflation of an intravascular balloon to cause flow arrest and allow for placement of coils without prolapse. Following coil placement, the balloon is deflated and removed and the coils are left in place. Stent-assisted coiling involves placing an intravascular stent designed for this purpose such as the Enterprise stent or LVIS Jr. stent and then deploying coils through the wall of the stent into the aneurysm sac. The main disadvantage of stent-assisted coiling is the requirement of dual antiplatelet therapy; however, pooled data from several studies has shown stent-assisted coiling to result in higher aneurysm obliteration rates as compared to balloon-assisted coiling. Complications of stent-assisted coiling are similar to those for coiling alone, with the added concern of in-stent thrombosis.

Flow Diversion

Flow-diverting stents are stents designed to promote flow stagnation within the aneurysm; in contrast to stents used for stent-assisted coiling, the metal coverage of flow-diverting stents is higher and the porosity is lower. Similar to stents used for stent-assisted coiling, use of a flow-diverting stent mandates dual antiplatelet therapy for a period of at least several months due to the risk of stent thrombosis. Typically, flow-diverting stents are employed for wide-neck or giant aneurysms in which coiling would not suffice. The Pipeline Embolization Device is the prototypical flow-diverting stent; it was studied in the Pipeline for Uncoilable or Failed Aneurysms study, in which a 73% occlusion rate was found as well as a 5.6% rate of major stroke or neurologic death. Similarly, the Surpass device, a more recently released flow-diverting stent, was studied in unruptured aneurysms deemed untreatable by coiling and found to have a 2.5% risk of SAH, 2.5% risk of intracerebral hemorrhage, and 3.7% risk of ischemic stroke with a 75% complete occlusion rate on follow-up angiogram. Risks inherent to flow-diverting stents include the risk of acute stent thrombosis, hemorrhagic complications due to antiplatelet use, and intimal hyperplasia within the body of the stent leading to stenosis of the vessel. An additional consideration of flow diversion is that aneurysm occlusion

is often delayed as compared to other methods such as coiling. Nevertheless, flow diversion has become an indispensable tool in the neurointerventionalist's arsenal for treating aneurysms that are not amenable to other methods.

Woven EndoBridge Intrasaccular Device

The Woven EndoBridge (WEB) device is a recent and novel endosaccular flow-diverting device, which is an ellipsoid device that is deployed into wide-neck aneurysms. The device is compressed within the microcatheter and is expanded into its final shape and detached electrothermically once the neurointerventionalist obtains satisfactory placement. European registry data from the WEB Clinical Assessement of Intrasaccular Aneurysm Therapy-2 (WEBCAST-2) study demonstrated a 1.8% risk of intraoperative rupture and an 8.0% retreatment rate with 80% of patients achieving successful aneurysm occlusion. Thromboembolic complications are a risk of WEB treatment, with incidence ranging from 4.7% to 15.6% depending on the series. Postoperative antiplatelet use varies between centers with wide heterogeneity, although in most cases, either aspirin or aspirin plus clopidogrel is administered for a variable length of time.

Intraluminal Support Device (PulseRider)

The PulseRider device is an intraluminal support device for wide-neck bifurcation aneurysms such as basilar tip aneurysms; it is an alternative to Y-stenting, where two crossing stents are placed to give support for coils to be placed in the sac of a bifurcation aneurysm. Six-month occlusion rates range from 87% to 100% depending on the series. A small prospective trial of 34 patients who underwent treatment with this device found procedural complications in 3 patients: one intraoperative rupture, one femoral artery dissection, and one thromboembolic event. At 6-month follow-up, 3 patients had neurologic events: one mild diplopia, one with coil-mass effect requiring subsequent stenting, and one occipital stroke after dual antiplatelet was interrupted for a procedure. Nevertheless, this device has a unique niche for treating challenging basilar tip aneurysms.

Subarachnoid Hemorrhage

Angiography is useful in making the diagnosis of cerebral aneurysm, potentially securing the aneurysm to decrease the risk of rerupture as well as treating symptomatic vasospasm due to SAH. As discussed earlier, previous studies (International Subarachnoid Aneurysm Trial and the Barrow Ruptured Aneurysm Trial) have found a lower risk of death and dependency in the endovascular as compared to clipping group, but there remains the potential for need for subsequent surgery or aneurysm recurrence.

A meta-analysis of five randomized controlled trials of clipping versus coiling in ruptured aneurysms found similar results, with not only a higher rate of poor outcome in the surgical cohort but also a higher rate of complete aneurysm occlusion.

Considerations when treating a ruptured aneurysm with endovascular treatment include the potential need for antiplatelet therapy; flow-diverting stent placement mandates dual antiplatelet therapy, which may be a concern in a patient who has experienced a recent SAH. Flow diversion also leads to delayed aneurysm thrombosis, raising concerns about leaving an aneurysm functionally unsecured until endothelialization takes place. A meta-analysis of flow diversion in ruptured aneurysms found a favorable clinical outcome in 81% of patients with SAH treated with flow diversion, a 5% risk of aneurysm rerupture with two-thirds of cases occurring within the first 24 hours, and a 12% risk of overall complications. The WEB device has also successfully been used to treat ruptured aneurysms, although experience is limited with this relatively new device compared to other methods. **Figure 25.4** demonstrates the breadth of techniques available for treating aneurysms endovascularly.

Vasospasm is a common complication of SAH, thought to be due to spasmogenic blood products causing dysregulation of the blood vessels; it occurs in 30% to 40% of patients with SAH. Currently accepted medical treatments for vasospasm include nimodipine for prophylaxis and hypertensive euvolemia as medical therapy. However, these are often not sufficient, and elevating blood pressure with vasopressors has potential cardiac side effects. Intra-arterial calcium channel blockers are often employed into vessels with symptomatic vasospasm; one retrospective study has shown that aggressive endovascular treatment of vasospasm with lower thresholds to treat is associated with a lower risk of delayed cerebral ischemia and a higher likelihood of favorable outcome as compared to more conservative management. Nimodipine is commonly employed for this purpose.

The patient has a fetal right posterior cerebral artery.

Acute Ischemic Stroke

Stroke remains the leading cause of disability and the second leading cause of death worldwide. The last two decades have seen a revolution in acute stroke therapy with the advent of alteplase and mechanical thrombectomy. In 1995, the National Institute of Neurological Diseases and Stroke (NINDS) trial showed that treatment with intravenous tissue plasminogen activator within 3 hours of the onset of ischemic stroke improved clinical outcome at 3 months LEVEL 1.[5] This window was extended to 4.5 hours based on the European Cooperative Acute Stroke Study (ECASS) trial.

In 2015, the Multicenter Randomized Clinical Trial of Endovascular Treatment for Acute Ischemic Stroke in the Netherlands reported significant improvement in 3-month outcome with no effect on mortality when tissue plasminogen activator followed by endovascular therapy was compared to endovascular therapy alone (33% vs 19% with good outcome) for strokes presenting within 6 hours of onset LEVEL 1.[6] This was a new revolution in acute stroke therapy and was followed by other similar trials. The Highly Effective Reperfusion Evaluated in Multiple Endovascular Stroke Trials collaboration was formed by the trial investigators of Endovascular Treatment for Small Core and Proximal Occlusion Ischemic Stroke, Extending the Time for Thrombolysis in Emergency Neurological Deficits—Intra-Arterial, Multicenter Randomized Clinical Trial of Endovascular Treatment for Acute Ischemic Stroke in the Netherlands, Pragmatic Ischaemic Stroke Thrombectomy Evaluation, Endovascular Revascularization With Solitaire Device Versus Best Medical Therapy in Anterior Circulation Stroke Within 8 Hours, Solitaire With the Intention for Thrombectomy as Primary Endovascular Treatment Trial, and Trial and Cost Effectiveness Evaluation of Intra-arterial Thrombectomy in Acute Ischemic Stroke. The Highly Effective Reperfusion Evaluated in Multiple Endovascular Stroke Trials meta-analysis has conclusively demonstrated the efficacy of mechanical thrombectomy in acute stroke treatment. The number needed to treat with endovascular thrombectomy to reduce disability by at least one level on modified Rankin Scale for one patient is 2.6.

The year 2018 saw another major revolution and change of guidelines for stroke treatment with extension of the stroke thrombectomy window to 24 hours in selected patients based on perfusion imaging scans as was seen in the DWI or CTP Assessment With Clinical Mismatch in the Triage of Wake Up and Late Presenting Strokes Undergoing Neurointervention With Trevo (DAWN) and EnDovascular ThErapy Following Imaging EvalUation for ISchemic StrokE 3 (DEFUSE 3) trials LEVEL 1.[7,8] **Figure 25.5** demonstrates an example of a large vessel occlusion of the basilar artery successfully treated with mechanical thrombectomy.

This pragmatic shift in treatment of acute strokes is attributed to careful patient selection as well as the advent of new technologies for clot extraction including stent retrievers, advanced aspiration systems, and balloon guide catheter systems.

Extracranial Carotid Artery Disease

Cervical internal carotid artery stenosis is an important cause of stroke; currently, revascularization is indicated in patients who have symptoms referable to the carotid artery who have 70% to 99% stenosis and considered in patients with 50% to 70% stenosis who have an acceptable operative risk of less than 6%. This benefit of revascularization for symptomatic carotid stenosis was shown by the North American Symptomatic Carotid Endarterectomy Trial and the pooled data from North American Symptomatic Carotid Endarterectomy Trial, Veterans Affairs trial, and European Carotid Surgery Trial LEVEL 1.[9,10] Asymptomatic carotid stenosis is treated on an individualized basis depending on operative risk; typically, carotid stenosis of more than 80% may be considered for treatment if the surgical risk is less than 3%. Carotid revascularization can occur via carotid endarterectomy (CEA) or via endovascular stent placement; each method has its relative advantages and disadvantages. CEA is associated with a higher cardiac risk relative to stenting; it also may be technically challenging in patients with a high carotid bifurcation (above the mandible) due to difficulty accessing the diseased segment. On the other hand, stent placement requires obligatory dual antiplatelet for a period of several months, which may have bearing on patients with a history of systemic bleeding or who may require other operations within the months following the stent placement. Stent placement is

also associated with a higher risk of ipsilateral stroke within the first 30 days. Patients older than 70 years benefit from CEA over carotid angioplasty and stenting due to a higher risk of perioperative stroke with stenting. However, in patients with high surgical risk or those with radiation necrosis or a history of prior CEA with restenosis, stent may be a preferred option.

Arteriovenous Malformations

AVMs are congenital anomalous vascular structures consisting of direct arterial-venous communications without an intervening capillary bed; they consist of a nidus that allows for high-flow arteriovenous shunting and are supplied by one or more feeding arteries and exhibit early drainage into surrounding venous structures. The most common presentation of AVM is intracerebral hemorrhage, accounting for over half of all presentations; however, seizures are the presenting symptom in about one-third of patients. The risk of hemorrhage is approximately 3% per year; however, this risk varies widely based on clinical and structural features of the AVM. Risk factors for hemorrhage include exclusively deep venous drainage, prior episodes of bleeding, intranidal aneurysm, history of prior hemorrhage, and presence of a single draining vein. **Figure 25.6** demonstrates an example of an AVM. Treatment of unruptured AVMs is controversial; A Randomized Trial of Unruptured Brain Arteriovenous Malformations found that medical management was associated with a lower risk of stroke and death than interventional treatment. However, there were issues with A Randomized Trial of Unruptured Brain Arteriovenous Malformations including a high crossover rate, relatively short follow-up period of only 33 months, and heterogeneity regarding type of intervention and individual risk factors associated with complications.

The Spetzler-Martin grading scale is the most widely used classification for grading AVMs and accounts for size, deep venous drainage, and location in eloquent cortex; it predicts outcomes after surgical excision. The scale ranges from 1 to 5, with lower scores indicating lower risk; 1 point is assigned for deep venous drainage, 1 point for the involvement of eloquent cortex, and the other points are assigned based on size (1 point for nidus <3 cm, 2 points for nidus 3-6 cm, and 3 points for nidus >6 cm). There are several strategies for managing AVMs including conservative management, microsurgical excision, stereotactic radiosurgery, and endovascular embolization. For low-grade AVMs, surgery alone may suffice; however, for higher grade lesions, a multidisciplinary staged approach is often employed. Endovascular embolization can be performed with a goal of complete cure, as an adjunctive treatment to preoperatively shrink the AVM prior to stereotactic radiosurgery or open microsurgery, or as a palliative treatment for inoperable AVMs to relieve hypoperfusion caused by arterial steal, when the AVM nidus shunts blood away from normal tissue. Endovascular embolization is performed most commonly by injecting liquid embolic agents into the AVM to occlude its arterial supply. Commonly used agents include Onyx (ethylene-vinyl copolymer, dimethyl sulfoxide, tantalum) and *n*-butyl cyanoacrylate (glue); embolic particles are also sometimes used as well as detachable coils. Caution is required to prevent inadvertently embolizing normal proximal arterial branches or obstructing normal venous outflow leading to venous infarct and hemorrhage; additionally, care must be taken to avoid precipitation of liquid embolic in the catheter, which can make it challenging or impossible to remove. One large retrospective study found a rate of 1.6% for permanent disabling neurologic complications, and 2.6% for permanent nondisabling neurologic complications.

Dural Arteriovenous Fistulas

Cranial or spinal dural arteriovenous fistulas (DAVFs) are acquired pathologic shunts between dural arteries and dural venous sinuses. The pathogenesis of DAVFs is unknown, although multiple associations have been described including anomalies of venous system, venous thrombosis, head trauma, transcranial surgery, association with pregnancy, delivery and menopause, increased systemic thrombotic activity, cortical vein thrombosis, role of hormonal changes (use of oral contraceptive and pregnancy) causing increased angiogenesis, tumors (meningiomas obstruct dural venous outflow), general surgery, otitis, and sinusitis. Signs and symptoms include pulse-synchronous tinnitus and exophthalmos, cranial nerve deficits, cognitive impairment, venous infarction, intracranial hemorrhage, and even death depending on fistula location, duration of disease, and venous drainage pattern. DAVFs are dynamic lesions that may either spontaneously regress or progress. For this reason, close clinical and radiologic monitoring is critical. Treatment should be pursued for all lesions with cortical venous drainage or intolerable symptoms. First-line management of DAVFs is endovascular

FIGURE 25.6 An arteriovenous malformation of the left frontal lobe (Spetzler-Martin grade IV) with arterial supply from left anterior cerebral artery **(A,B)** *(black arrows)* and right anterior cerebral artery **(C,D)** *(white arrows)*. **D:** Early venous drainage is noted into the superior sagittal sinus *(black arrow)*.

embolization via the transarterial route, transvenous route, or a combination of both. Transarterial embolization is typically performed with a liquid embolic agent such as *n*-butyl cyanoacrylate or Onyx. Transvenous embolization is performed by retrograde catheterization of the involved dural sinus or cortical vein followed by deposition of coils and/or liquid embolic material at the site of inflow of the arteriovenous shunt. Transvenous embolization has been shown to have a high likelihood of cure and is often used to treat transverse/sigmoid sinus and cavernous sinus DAVFs. Detachable coils are deployed to form a scaffolding, after which pushable fibered coils, which are more thrombogenic and much less expensive, can then be added to achieve complete occlusion of the venous segment.

Other Diagnostic Uses

Diagnostic cerebral angiography can also be employed as a purely diagnostic tool; it is useful in classifying the severity of moyamoya disease and both arteritic and nonarteritic vasculopathies such as fibromuscular dysplasia or vasculitis. It is often used in the diagnosis of reversible cerebral vasoconstriction syndrome, although this indication is beginning to be supplanted by noninvasive imaging in some cases. Vessel wall imaging with high-resolution magnetic resonance imaging has emerged as an area of ongoing research in visualizing luminal properties noninvasively; at this time, the comparative utility relative to angiogram is unknown, but it is likely to become more widely used particularly in imaging atherosclerosis and suspected vasculitis. Angiography is also important in the preoperative evaluation of patients undergoing ablative surgery for epilepsy or tumor resection; the Wada test involves intra-arterial injection of a barbiturate to evaluate hemisphere dominance for language. In some centers, however, functional magnetic resonance imaging is becoming a preferred modality for this purpose.

EMERGING CONSIDERATIONS

Chronic Subdural Hematoma

Chronic subdural hematoma is a challenging condition to manage particularly in the elderly population; often, these patients require antiplatelet or anticoagulation for concomitant cardiac conditions, and this complicates management. Surgery is a commonly accepted treatment, but some series have reported recurrence rates of 8% to 15% in some modern series. It is theorized that in chronic subdural hematoma, abnormal "neomembranes" develop after liquefaction of the subdural hematoma, causing collagen synthesis and fibroblast deposition; these neomembranes are supplied via branches of the middle meningeal artery. Obliterating the blood supply by endovascular embolization of middle meningeal artery branches has been shown to successfully resolve the chronic subdural hematoma; a recent meta-analysis of 15 studies demonstrated a low recurrence rate of 3.6% in patients undergoing middle meningeal artery embolization. Operative techniques vary between neurointerventionalists; however, the general premise involves first selectively catheterizing the external carotid artery ipsilateral to the subdural hematoma and ensuring that no "dangerous anastomoses" exist between the external carotid artery and internal carotid artery and vertebral artery. This is crucial because inadvertent spread of embolic particles from the middle meningeal artery branches into branches of the ophthalmic, ascending pharyngeal, or other branches can lead to neurologic deficits. Once a safe embolic trajectory is ascertained, a combination of coils and embolic particles, or particles in isolation, is injected into the middle meningeal artery until successful embolization has been achieved.

Idiopathic Intracranial Hypertension

Idiopathic intracranial hypertension (IIH), also known as *pseudotumor cerebri*, is a condition in which intracranial pressure is elevated in the absence of a mass lesion; risk factors include obesity, female sex, and certain medications. IIH can cause tinnitus, headaches, and both transient and permanent vision loss. Treatment strategies include topiramate or acetazolamide, weight loss, optic nerve sheath fenestration, and ventriculoperitoneal shunting; additionally, transverse sinus stenting is another potential strategy for managing IIH. In a series of 143 patients treated with transverse sinus stenting, the authors reported a 6% rate of combined major and minor procedural complications, an 88% rate of headache improvement, and an 87% rate of visual symptom improvement. Meta-analysis of 20 articles and 474 patients who underwent venous sinus stenting found over 90% improvement in papilledema, 90% improvement in pulsatile tinnitus, and a major complication rate defined as subdural hematoma or SAH of 1.9%. All patients who had an intracranial hemorrhage made a full recovery. A small prospective study of 13 patients also reported high success rates with transverse sinus stenting in terms of headache improvement, reduction in visual symptoms, and resolution of pulsatile tinnitus. The current data suggests that transverse sinus stenting can be beneficial in selected patients with IIH.

Intracranial Stenting

Intracranial atherosclerosis is a common cause of stroke; it is particularly prevalent in Asians, accounting for up to 30% to 50% of strokes in this population. It is known that greater than 80% stenosis in the symptomatic vessel correlates with a high risk of recurrent stroke; thus, revascularization with stenting has been studied in several trials. Two randomized controlled trials have studied the utility of intracranial stenting in patients with symptomatic intracranial atherosclerosis; the Stenting and Aggressive Medical Management for Preventing Recurrent Stroke in Intracranial Stenosis (SAMMPRIS) found that medical management was associated with a lower risk of stroke and death than endovascular treatment. Likewise, the Vitesse Intracranial Stent Study for Ischemic Stroke Therapy found higher rates of stroke and death in the procedural group compared to the medical arm; however, the study was stopped prior to target enrollment after the results of SAMMPRIS were published. However, it is notable that these studies were undertaken with earlier generation stents, which may have had higher complication rates than newer technology. Case series with newer stents such as the Enterprise stent have reported complication rates as low as 1.5% with one SAH in a series of 68 patients. Additionally, both SAMMPRIS and Vitesse Intracranial Stent Study for Ischemic Stroke Therapy excluded patients with ongoing progressive neurologic symptoms. It is this latter group of patients, whom are experiencing ongoing and progressive ischemic events, that may arguably be the most likely to benefit from a stent. Submaximal angioplasty has been proposed as an

alternative to stenting with several published case series but has not been studied as extensively as stenting. Further studies in a carefully selected patient population with modern devices are necessary to evaluate the potential benefit of stenting in intracranial atherosclerosis; until then, stenting of the intracranial arteries is generally reserved as a rescue measure for patients with severe, progressive neurologic deficits refractory to maximal medical therapy.

Tumors

Microcatheters have allowed for superselective catheterization of intracranial vessels; this ability has allowed for the use of neuroendovascular therapy in the treatment of intracranial tumors. There are two major methods of treating intracranial tumors endovascularly: embolization of the blood supply of the tumor and infusion of intra-arterial chemotherapy into the vascular supply of the tumor. In patients undergoing arterial embolization, a Japanese registry data of over 40,000 patients found a procedural complication risk of 3.7%; meningioma accounted for the vast majority of tumors in this study. Superselective intra-arterial infusion of chemotherapy is an area of active research, and feasibility has been demonstrated in several small series, although further research is needed on this topic.

SUMMARY

Neuroendovascular treatments have evolved into a rapidly expanding field with the previous sections covering the most common applications. There are many additional procedures that fall under the realm of neuroendovascular therapy, which are beyond the scope of this chapter; examples include petrosal sinus sampling, sphenopalatine artery embolization for epistaxis, treatment of congenital vein of Galen malformations, carotid-cavernous fistulas, kyphoplasty, and vertebroplasty, among others. As technology continues to improve, the limitations of vessel caliber become less of an issue; aneurysms, which could previously not be accessed are now candidates for endovascular treatment, and strokes caused by distal middle cerebral artery branch occlusions are now being regularly treated at some centers. The myriad of treatments discussed in this chapter illustrates the broad scope and applications of endovascular neuroradiology.

26 Electroencephalography and Evoked Potentials

Nicolas Gaspard and Emily J. Gilmore

KEY POINTS

1. Electroencephalography (EEG) is a widely used tool that allows for the functional assessment of the central nervous system integrity.
2. EEG is the single most important ancillary test for the diagnosis of epilepsy and the characterization of patient's spells.
3. EEG identifies which patients with acute confusion or obtundation suffer from nonconvulsive seizures and provides prognostic value after traumatic and anoxic brain injuries.
4. Evoked potentials are an extension of the neurologic examination by providing objective confirmation of a lesion that may have been suggested by ambiguous or subtle signs or symptoms.
5. Magnetoencephalography, as a complement to EEG, noninvasively localizes epileptic foci in patients with drug-refractory epilepsy and presurgical functional mapping of eloquent cortical areas.

FIGURE 26.1 The International 10-20 system. The International 10-20 system is a conventional method used to place scalp electrodes for electroencephalography recordings. Electrodes bear labels referring to their anatomic locations in relationship to cortical areas (T for temporal, Fp for frontopolar, F for frontal, C for central, P for parietal, and O for occipital). Even and odd numbers refer to right and left hemispheric locations, respectively, whereas Z is used to denote midline electrodes. Inter-electrode distances are calculated as 10% or 20% of the total anterior-posterior or right-left distance of the skull along specific lines *(dotted lines)*. These lines are drawn between anatomic landmarks, such as the nasion, the inion, and the tragus. Ear electrodes (A1 and A2) are located on the earlobes or behind the ears on the mastoid bones. Additional electrodes are usually placed to record eye movements (electrooculogram) and electrocardiogram.

ELECTROENCEPHALOGRAPHY

Introduction

Electroencephalography (EEG), evoked potentials (EPs), and magnetoencephalography (MEG) measure the electromagnetic activity generated by neural structures. They allow for the functional assessment of the central nervous system and are often complimentary to imaging studies. Electrophysiologic studies are especially important to the differential diagnosis when neurologic disorders are unaccompanied by detectable alterations in brain morphology. This chapter is an overview of the current capabilities and limitations of these techniques in clinical practice. There are numerous published guidelines, many of which are publically available and beyond the scope of this chapter. See references for further details.

Normal Electroencephalography

The EEG measures electrical potentials resulting from the summation of the postsynaptic activity of cortical neurons. Although generated by cortical cells, these potentials are influenced by ascending projections from subcortical structures such in the thalamus and upper brainstem. Most commonly, the EEG is recorded with electrodes placed on the scalp, following a conventional method based on anatomic landmark called the *International 10-20 system* (Fig. 26.1). The scalp EEG presents a very low resolution view of electrical activity of the brain that favors contributions from the lateral convexities due to attenuation and blurring from overlying tissue layers.

The EEG varies greatly with the state of arousal. The main feature of the normal EEG during wakefulness in adults is the posterior dominant rhythm, also called *alpha rhythm*. This rhythm consists in an 8 to 13 cycle per second (cps) sinusoidal activity that is best observed over the parietal and occipital regions bilaterally (Fig. 26.2). In a relaxed individual, the alpha rhythm manifests with eye closure and attenuates with alerting or eye opening. Faster activity, in the 14 to 30 cps range, called *beta activity*, can be observed in health individuals during wakefulness, usually

FIGURE 26.2 Normal electroencephalography in an awake 37-year-old man. The posterior dominant rhythm *(dashed lines)* is in the alpha frequency range, is symmetrical, and attenuates with eye opening.

in the frontocentral regions. It can also be seen with a broader distribution during drowsiness (Fig. 26.3) and is enhanced in individuals taking benzodiazepines or barbiturates.

EEG interpretation and reporting should attempt to follow well-defined terminology.

Sleep is divided in four stages on the basis of EEG, eye movements, and muscle activity. Stage N1, or drowsiness, is characterized by the disappearance of the posterior dominant rhythm, which is replaced by low-voltage slower activity. Sharp waves maximal at the vertex, called *vertex sharp waves*, also occur. Stage N2 is defined not only by the presence of sleep spindles (12-14 cps sinusoidal activity that is maximal over the central regions) but also features vertex sharp waves, K complexes (large amplitude diphasic slow waves usually brought up by auditory stimulation and often occurring in close temporal proximity to a spindle [Fig. 26.4]), and positive occipital sharp transients of sleep (surface-positive check mark–like waveforms occurring singly or in trains in the occipital regions). Slow waves of sleep (0.5-1 cps) progressively occupy most of the recording during stage N3. During rapid eye movement (REM) sleep, the EEG resembles the EEG of drowsiness, but REM and general atonia are present. In adults, REM occurs about 90 minutes after sleep onset and thus is not usually seen on routine studies.

EEG activity undergoes major changes with age. In neonates, these changes occur on a nearly daily basis, and knowledge of the conceptional age is required for proper interpretation. Sleep-wake cycles can be identified on the basis of characteristic EEG patterns that are beyond the scope of this chapter. A posterior dominant rhythm that is reactive to eye opening becomes visible in most children by 4 months of age. With increasing age, the frequency of the posterior dominant rhythm progressively increases, reaching 6 cps in most children at 1 year and 8 cps in most children at 4 years. Sleep spindles appear at 2 months but do not become synchronous in most children until the age of 2 years. Normal delta activity persists during wakefulness through childhood, adolescence, and early adulthood but becomes progressively less prominent and more intermittent and restricted to the posterior regions (*posterior slow wave of youth*).

Abnormal Electroencephalography

Epilepsy

The EEG is the most single important ancillary test for the diagnosis of epilepsy. Epileptiform discharges include spikes (<70 ms), polyspikes, sharp waves (70-200 ms), spike-and-slow-wave complexes, and sharp-and-slow-wave complexes. Other nonspecific findings in epilepsy include focal polymorphic slowing and intermittent rhythmic delta activity.

Not only can the presence of epileptiform discharges (EDs) confirm a clinical suspicion of epilepsy, but the localization and type of discharge also helps to identify the diagnosis of a specific syndrome (Table 26.1). A proper syndromic classification is paramount to ensure adequate management because different syndromes may call for different treatments. It should be noted that EDs may occasionally be absent in a minority of patients who have epilepsy. The first routine EEG obtained after an inaugural seizure demonstrates EDs in approximately 30% to 50% of cases. This proportion increases to a maximum of 80% to 90% after the third routine EEG, and subsequent EEGs do not raise this proportion further. Longer recordings, sleep recordings, and so-called activation procedures, such as hyperventilation, intermittent photic stimulation, and sleep deprivation can be performed to increase the sensitivity of the EEG.

FIGURE 26.3 Normal electroencephalography in a 42-year-old man during drowsiness. Beta activity with a broad distribution.

Conversely, EDs are seen in 1% to 2% of EEGs of individuals without a history of epilepsy. This proportion is higher in children and in siblings of patients with epilepsy.

In addition to diagnosis, EEG results also help with the management of epilepsy. A finding of interictal EDs after a single seizure increases the likelihood of seizure recurrence and therefore influences the decision about whether to treat with antiepileptic drugs. Similarly, the presence of interictal EDs increases the likelihood of seizure recurrence when consideration is being given to discontinuing antiepileptic drugs after a period of seizure control. Finally, in the setting of convulsive status epilepticus, EEG can be extremely helpful in determining whether individuals with prolonged postictal cognitive impairment (usually >30 min) are experiencing electrographic seizures (up to 50%) or nonconvulsive status epilepticus (up to 14%).

Finally, so-called benign epileptiform variants should not be confused for *bona fide* EDs. These variants are physiologic activity with a somewhat sharp morphology that may resemble spikes or sharp waves but can be readily dismissed after careful inspection. This distinction is important because it is not uncommon to encounter patients who carry a diagnosis of medically refractory epilepsy but turn out to have nonepileptic spells and in whom a normal variant has been mislabeled as an ED.

Focal Brain Lesion or Dysfunction

With the advances of brain imaging, the usefulness of EEG for the diagnosis of focal brain injury has significantly decreased. However, EEG remains the only way to assess the epileptogenic potential of a cerebral lesion. The hallmark of focal brain injury is the presence of localized nonrhythmic delta (1-4 cps) or theta (5-7 cps) activity, referred to as *focal polymorphic slowing* (**Fig. 26.5**). As a rule of thumb, delta activity is associated with more destructive lesions than theta activity. *Focal attenuation of fast activity*, the absence of normal alpha or beta (14-30 cps) activity over a region of the scalp indicates focal cortical injury. Both focal slowing and attenuation can be seen in the absence of a focal lesion (**Fig. 26.6**). In this case, they represent the presence of focal cerebral dysfunction as a result of a postictal state or, rarely, migraine. *Lateralized periodic discharges* (LPDs; also referred to as *periodic lateralized epileptiform discharges*) usually indicate the presence of an acute destructive lesion with a high epileptogenic potential, usually stroke, neoplasm, or encephalitis because up to 85% of patients will experience

FIGURE 26.4 Normal electroencephalography in a 25-year-old man during stage N2 sleep. Sleep spindles *(dashed boxes)* and K complex *(solid box)*.

seizures during the acute phase of their illness (Fig. 26.7). They can occasionally be seen in the aftermath of a seizure in patients with chronic epilepsy or with a remote brain injury. Rarely, LPDs are associated with clinical manifestations (time-locked contralateral myoclonus, visual hallucinations, etc.).

Diffuse Brain Dysfunction or Injury

Toxic, metabolic, diffuse hypoxic-ischemic, and other global insults to the brain result in generalized nonspecific EEG changes. Mild encephalopathy is characterized by slowing of the posterior dominant rhythm and a generalized excess of polymorphic theta activity. With more pronounced brain dysfunction, the posterior dominant rhythm is lost and replaced by a mixture of theta and delta activity. These changes are described as *generalized polymorphic slowing*. In more severe cases, cerebral activity consists mostly of delta activity, which may become monotonous. At this point, *reactivity to external stimulation* (noise, noxious stimuli) may be lost. In the most severe forms of encephalopathy, there is attenuation (<20 μV) or even suppression (<2 μV) of all cerebral activity. A *suppression-burst pattern* in which periods of suppression alternate with bursts of high amplitude activity can also be seen in severe cases (Fig. 26.8). *Generalized rhythmic delta activity*

TABLE 26.1 Electroencephalography (EEG) Features of Major Epileptic Syndromes

Syndrome	EEG Features
Ohtahara syndrome	Suppression-burst pattern during sleep and wakefulness
Early myoclonic encephalopathy	Suppression-burst pattern during sleep
West syndrome	Hypsarrhythmia (highly disorganized background with arrhythmic and asynchronous high-amplitude slow waves and multifocal spikes)
Lennox-Gastaut syndrome	Slow (<2.5 cps) generalized spike-and-wave complexes Generalized paroxysmal fast activity Slowed background
Benign idiopathic focal epilepsy of childhood	Focal (often bilateral independent or multifocal) sharp waves or spikes Normal background
Childhood absence epilepsy	≥3 cps generalized spike-and-wave complexes Normal background
Juvenile myoclonic epilepsy	≥3 cps (often up to 6 cps) generalized spike-and-wave and polyspike-and-wave complexes Normal background
Localization-related epilepsy	Focal spikes, sharp waves, or spike-and-wave complexes Sometimes focal polymorphic or rhythmic slow activity

FIGURE 26.5 Diffuse slowing in a 72-year-old woman with sepsis. The posterior dominant rhythm is not visible. The background consists of admixed theta and delta activity.

FIGURE 26.6 Focal slow (polymorphic delta) activity *(boxes)* with attenuation of the posterior dominant rhythm *(dashed lines)* over the right hemisphere in a 64-year-old woman with a glioblastoma multiforme.

FIGURE 26.7 Left hemispheric lateralized periodic discharges *(boxes)* at approximately one per second in a 52-year-old man with herpes encephalitis.

FIGURE 26.8 Suppression-burst pattern following cardiac arrest in a 54-year-old man. Periods of suppression are interrupted by bursts of sharply contoured delta and theta activity.

FIGURE 26.9 Generalized periodic discharges with triphasic morphology (triphasic waves) at 1.5 per second in a 35-year-old man with acute liver failure. Each discharge consists of three phases: (1) a small-amplitude negative sharp wave followed by (2) prominent positive sharp wave and (3) a negative slow wave.

(often frontal and intermittent) is another nonspecific finding of encephalopathy, although it can be seen with lesions in the frontal lobes. *Generalized periodic discharges* (GPDs) are repetitive waveforms that occur either at periodic or quasiperiodic intervals of 0.5 to 3 cps. They can be encountered in any type of encephalopathy, at a moderate to severe stage, and are associated with an increased risk of seizures. *Triphasic waves* are a subtype of GPDs with a typical morphology (**Fig. 26.9**). They were initially thought to be specific of hepatic encephalopathy. They can in fact be seen in most metabolic or toxic encephalopathies and even during or after status epilepticus. A major role of the EEG in patients with acute confusion or obtundation is to identify those who suffer from nonconvulsive status epilepticus.

Neurodegenerative disorders affecting the cortex and subcortical structures can be associated with similar nonspecific findings, albeit most often mild (ie, slowing of the posterior dominant rhythm, diffuse excess of theta activity, and frontal and intermittent rhythmic delta activity).

Occasionally, the EEG discloses patterns that point toward a specific diagnosis. In Creutzfeldt-Jakob disease, severe disruption of the background and periodic discharges (LPDs or more commonly GPDs) occur, always within 3 months after the onset. Huntington disease is associated with a progressive attenuation of cerebral activity. At least 50% of patients with anti–*N*-methyl-D-aspartate receptor encephalitis show a typical pattern of rhythmic delta activity overridden by beta activity, which has been termed *extreme delta brush* due to its resemblance to normal delta brushes of neonates.

Long-term Monitoring

Epilepsy Monitoring Unit

Long-term EEG monitoring, simultaneously with audio and video recording, can be performed in dedicated epilepsy monitoring units to not only capture interictal epileptiform activity but also characterize patients' typical spells. These recordings are useful to clarify the nature of spells of uncertain etiology and assist in the determination of seizure type and epilepsy syndrome (**Figs. 26.10** and **26.11**). The EEG shows typical changes in all patients during generalized or focal impaired awareness seizures (previously referred to as *complex partial seizures*) but can remain normal during focal awareness seizures (previously referred to as *simple partial seizures*). In patients with medically refractory epilepsy, long-term monitoring provides invaluable electroclinical correlations that will contribute to the assessment of potential candidates for resective surgery. If the results of monitoring with scalp EEG and other ancillary tests (magnetic resonance imaging, positron emission tomography scan with ^{18}F-fluorodeoxyglucose, etc.) are inconclusive, patients may benefit from invasive EEG, either with cortical electrodes (electrocorticography [ECoG]) or with depth electrodes implanted stereotactically (stereo-EEG). These invasive studies offer better spatial resolution and can identify a seizure focus that was not detected or well circumscribed with scalp EEG. Invasive recordings also allow the investigation of EEG activities in frequency bands that are outside the conventional bands (0.5-30 cps), which can be reliably studied with scalp EEG. These activities include infraslow activity

FIGURE 26.10 Three-cycle-per-second generalized spike-and-wave complexes in a 6-year-old girl with childhood absence epilepsy.

FIGURE 26.11 Left temporal spike-and-wave discharges in a 32-year-old man with mesial temporal lobe sclerosis and epilepsy. The discharges *(boxes)* are maximal over the left anterior inferior temporal region (F7, T3, F9, and T9).

(<0.5 cps) and high-frequency oscillations (ripples [80-250 cps], fast ripples [250-500 cps]; and very high-frequency oscillations [500-2,000 cps]). Studies in the past decade have shown that both infraslow activity and high-frequency oscillations provide useful information for the localization of the seizure focus. Finally, invasive studies permit the delineation of functional cortical areas through electrical cortical stimulation mapping.

Intraoperative Neuromonitoring

Given the exquisite sensitivity of cortical neurons to ischemia, the EEG can detect reduction in cortical perfusion at an early and reversible stage. This can be advantageously used to monitor for cerebral ischemia secondary to carotid clamping during carotid endarterectomy. EEG monitoring may identify those patients who would benefit from the use of a vascular shunt during the procedure in order to restore adequate perfusion. Conversely, shunts, which have an associated risk of complications, can be avoided in those patients in whom the EEG remains normal. EEG monitoring has also been advocated during cardiac and aortic surgery, but its use in this indication has been limited to selected academic centers.

ECoG can be used during awake neurosurgery to map functional cortical areas and to delineate the critical limits of a resection. Intraoperative ECoG recordings can also be used to identify epileptogenic regions for resection.

Critical Care Electroencephalography Monitoring

Continuous EEG monitoring is increasingly used in the critical care setting LEVEL I.[1] These prolonged recordings are currently indicated to detect and monitor treatment of nonconvulsive seizures, clarify the nature of abnormal motor activity, and monitor brain function during drug-induced coma.

Between 15% and 20% of critically ill patients develop seizures during their acute illness. Half of them will develop status epilepticus. Risk factors include acute brain injury, a chronic seizure disorder, younger age, sepsis, and severe alteration of consciousness (ie, stupor and coma). Up to 90% of these seizures are nonconvulsive and will be missed if EEG monitoring is not performed. There is mounting evidence that nonconvulsive seizures have detrimental metabolic and hemodynamic effect and contribute to secondary brain injury and poorer outcome. A monitoring period of 24 hours is required to detect 90% of these seizures. A longer period is required in comatose patients and in patients with LPDs. A 60-minute EEG will miss half of the patients who have seizures. Episodes of abnormal spontaneous motor activity do not always correspond to seizures. Nonepileptic myoclonus, tremor, clonus, and rigors are frequent among acutely ill patients. Continuous EEG monitoring will help clarify the nonepileptic nature of these episodes and avoid the unnecessary and potentially harmful prescription of antiepileptic drugs. Deep sedation with high-dose barbiturates is sometimes performed to control refractory intracranial hypertension. In this indication, the EEG is used to monitor sedation, with the aim of maintaining a suppression-burst pattern.

EEG abnormalities have prognostic values after traumatic and anoxic brain injury. Malignant patterns of suppression-burst, suppression, and low-voltage unreactive widespread delta activity are almost invariably associated with poor outcome. Other possible applications of EEG monitoring include early detection of delayed cerebral ischemia after aneurysmal subarachnoid hemorrhage.

In addition to seizures, cortical spreading depolarizations are increasingly recognized phenomena in acute brain injury and are associated with outcome, particularly in traumatic brain injury. Animal and human studies have demonstrated that cortical spreading depolarizations contribute to secondary brain injury in traumatic brain injury, expansion of ischemic stroke, and both early brain injury and delayed cerebral ischemia after subarachnoid hemorrhage.

EVOKED POTENTIALS

Introduction

EPs are potentials generated by the nervous system in response to stimuli.

Somatosensory, auditory, and visual pathways can be investigated using simple sensorial stimulation and recording from neural structures, whereas motor pathways are explored by transcranial magnetic stimulation of the motor cortex and recording of muscle response. EPs have a low signal-to-noise ratio, being of much lower amplitude than spontaneous activity, and require the averaging of a large number of responses to be identified.

Clinically, EPs are functional tests, which can be viewed as an extension of the neurologic examination. They can provide objective confirmation of the existence of a lesion that may have been suggested by ambiguous or subtle signs or symptoms. Additionally, they can also reveal dysfunction of sensory pathways that is not clinically apparent. Finally, they have the capacity to localize a suspected lesion.

EPs are composed of a stereotyped sequence of waveforms that are labelled by their polarity (negative [N] or positive [P]) and their peak latency from the time of stimulation (expressed in milliseconds). Dysfunction of sensory or motor pathways due to disease or injury leads to increased waveform latency, whereas complete interruption of conduction or destruction of the neural generators results in the absence of waveforms.

Somatosensory-Evoked Potentials

Somatosensory-evoked potentials (SSEPs) are elicited by light electrical stimulation of peripheral nerves and reflect sequential activation of structures along the afferent sensory pathways, principally the dorsal column lemniscal system. Upon stimulation of the median nerve, the following responses are clinically useful: First, the N9 (Erb's point potential), representing the afferent volley entering the brachial plexus; the N13, generated by postsynaptic activity in the gray matter of the spinal cord; the P14, generated by the caudal medial lemniscus in the lower brainstem; the N18, generated by the rostral brainstem; and, finally, the N20, reflecting the activation of the somatosensory cortex. Similar responses can be recorded upon stimulation of the posterior tibial nerves from which the following responses are clinically useful: First, the lumbar potential (LP)/N22, recorded from the T12 spinal process, represents the afferent volley entering the dorsal roots and dorsal root entry zone; the N34, recorded at the cervical spine, is thought to represent the brainstem or perhaps thalamus; P37/P38, referred to as *the scalp potentials*, reflect activation of the somatosensory cortex (**Fig. 26.12**).

SSEPs are altered by most conditions affecting the somatosensory pathways, including stroke, tumors, traumatic injury, and demyelinating disorders. They are abnormal in 50% to 60% of patients with multiple sclerosis, even in the absence of clinical signs or symptoms.

FIGURE 26.12 Technique for obtaining either upper or lower extremity somatosensory-evoked potential (SSEP) and normal SSEPs obtained by stimulation of the median nerve at the wrist. Abbreviations: ear ref, ear reference; Fr_C, frontal contralateral; Par_C, parietal contralateral.

SSEPs are increasingly used for prognostication in comatose patients after anoxic or traumatic brain injury. The absence of N20 after the rewarming period is almost invariably associated with a poor outcome (Fig. 26.13).

SSEPs are also commonly used to monitor the integrity of the spinal cord during high-risk neurosurgical, orthopedic, and vascular interventions. They are also increasingly used to monitor the integrity of the brain function during high-risk cardiovascular surgery because loss of the N20 indicates early ischemia at a reversible stage.

Visual-Evoked Potentials

Visual-evoked potentials (VEPs) are obtained by stimulation with an alternating checkerboard pattern of black and white squares (ie, white squares change to black and vice versa at a regular frequency). This stimulation with pattern reversal produces an occipital positive response with a mean latency of 100 milliseconds (P100). VEPs are performed for each eye individually. Because fibers from the temporal side of the retina decussate at the optic chiasm, an abnormal P100 after stimulation of one eye implies the presence of a prechiasmatic lesion, affecting the retina or the optic nerve on the side of the stimulation. An abnormal P100 upon stimulation of both eyes may be caused either by bilateral prechiasmatic and/or retrochiasmatic lesions. Unilateral retrochiasmatic lesions usually do not significantly alter the P100. Acute optic neuritis is initially accompanied by an attenuation of the P100 (Fig. 26.14). In the postacute phase, although the P100 may return to almost normal amplitude, it is significantly delayed. Abnormal VEPs are found in up to 70% of patients with multiple sclerosis, even in the absence of a history of optic neuritis. These findings are nonspecific and can also be seen in other conditions, including demyelinating disorders (acute disseminated encephalomyelitis, anti–neuromyelitis optica spectrum), ischemic optic neuropathy, compression of the optic nerve, cataracts, glaucoma, toxic and metabolic optic neuropathy, degenerative disorders, and retinal disease. In the setting where a patient reports visual loss, a normal VEP strongly favors a psychogenic disorder (ie, hysteria or malingering).

Brainstem Auditory–Evoked Responses

Brainstem auditory–evoked potentials (BAEPs) consist of five waveforms, labelled I to V, of which waves I, III, and V are the most important from a clinical point of view. The nature of the generators of the responses is largely unclear but it is believed that wave I is generated by the peripheral portion of the acoustic nerve, whereas waves III and V are probably generated in the brainstem by the superior olivary complex and the inferior colliculus, respectively.

BAEPs are abnormal in most cases of tumors of the cerebellopontine angle, such as acoustic neuroma. Abnormalities include delay or absence of all waves after wave I and absence of all waves (Fig. 26.15).

BAEPs are also sensitive to lesions affecting the auditory pathways in the brainstem. They are almost always abnormal in

FIGURE 26.13 Somatosensory-evoked potentials obtained by stimulation of the median nerves at the wrist in a patient with postanoxic brain injury. N13 and P14 potentials, generated in the brainstem, are identified. N20 potentials, generated in the cortex, are not identified, indicating a poor prognosis. Abbreviations: CHN, channels; Par_C, parietal contralteral; Parl, parietal ipsilateral. (Courtesy of Nicolas Mavroudakis, MD, PhD.)

FIGURE 26.14 Visual-evoked potentials in patient with probable multiple sclerosis. The P100 after stimulation of the left eye is normal, whereas there is a significant delay after stimulation of the right eye. (Courtesy of Nicolas Mavroudakis, MD, PhD.)

the case of intrinsic tumors of the brainstem. They are preserved when the auditory pathways are spared because may occur in vascular lesions of the pontine tegmentum causing a locked-in syndrome. BAEPs abnormalities are frequent in patients with multiple sclerosis and in other demyelinating conditions.

In comatose patients, BAEPs are normal when the cause is metabolic or toxic. They are abnormal when the brainstem is directly affected between the midbrain and the lower pons by a primary infratentorial lesion or by herniation due to a supratentorial mass. The absence of all waves subsequent to wave I carries a poor prognosis, whereas the presence of wave V is associated with good outcome. BAEPS are relatively insensitive to sedative drugs, including anesthetic doses of barbiturates. They can be used as a confirmatory test of brain death, even in the presence of doses of barbiturates that induce an isoelectric EEG. Absence of all waves or the sole persistence of wave I indicates brain death.

FIGURE 26.15 Brainstem auditory–evoked potentials in a patient with a meningioma in the right pontocerebellar angle. With left stimulation, waves I to V are identified and have a normal latency. With right stimulation, only wave I (generated in the peripheral acoustic nerve) is identified; subsequent waves generated in the brainstem are not visible, indicating impairment of auditory pathways in the right pons and/or midbrain. (Courtesy of Nicolas Mavroudakis, MD, PhD.)

Motor-Evoked Potentials

Motor-evoked potentials assess the integrity of motor pathways. They are elicited by transcranial magnetic stimulation of the primary motor cortex. Muscle compound potentials are recorded and the latency of response can be measured. Stimulation can also be delivered at the spinal cord level allowing for calculation of central conduction time by subtracting the latency after spinal cord stimulation from the latency after cortical stimulation (Fig. 26.16). MEPs are increasingly used in association with SSEPs to monitor spinal cord integrity during surgery.

MAGNETOENCEPHALOGRAPHY

MEG allows the noninvasive measure of magnetic fields generated by the electrical activity of cortical neurons. Magnetoencephalographic recordings rely on the technology of superconducting quantum interference device, which need to be constantly cooled by liquid helium at −270°C (−452°F) in a cryogenic vessel. Because external magnetic noise is several orders of magnitude larger than neuromagnetic fields, a shielded room is required. MEG is usually combined with magnetic resonance imaging volumetric scans to provide accurate localization of the sources of the magnetic fields, a process called *magnetic source imaging*. Contrary to scalp EEG that records activity from radially oriented electric dipoles, MEG records activity from tangential dipoles because magnetic fields are orthogonal to the electric activity by which they are generated. MEG is, thus, able to investigate regions that are poorly accessible to scalp EEG recordings, such as the insula and opercular cortex, and, in general, provides information that is complementary to EEG.

The current clinical applications of MEG are noninvasive localization of epileptic foci in patients with drug-refractory epilepsy and presurgical functional mapping of eloquent cortical areas.

FIGURE 26.16 Motor-evoked potentials by transcranial magnetic stimulation of the motor cortex and by stimulation of the cervical spinal cord. The response is recorded with surface electromyogram electrodes over the first dorsal interosseous. The delay between the two responses is the central conduction time in the corticospinal tract. Abbreviations: CCT, central conduction time; STIM, stimulation. (Courtesy of Nicolas Mavroudakis, MD, PhD.)

The American Clinical MEG Society and the International Federation of Clinical Neurophysiology have published practical guidelines for clinical MEG.

KEY POINTS

1. Electrodiagnostic studies can assess many motor and sensory nerves and the majority of skeletal muscles, but each study must be tailored to the clinical condition in question.
2. Nerve conduction studies separately test sensory and motor fibers and may demonstrate axonal loss, focal processes and compression, or generalized demyelination.
3. Needle electromyography studies can distinguish neurogenic from myopathic weakness.
4. Studies are often an extension of the neurologic exam and not a predetermined protocol.
5. Many technical factors or challenges must be avoided in order to have reliable data and conclusions.
6. Testing is often considered neuromuscular physiology, which is complementary to anatomic imaging tests, for example, magnetic resonance imaging, computed tomography, and ultrasound.
7. Specialized techniques are employed in certain situations, such as repetitive nerve stimulation, single-fiber electromyography, and transcortical magnetic stimulation.
8. Transcortical magnetic stimulation is an emerging treatment as well as testing modality.

INTRODUCTION

Advances in electronics enabled clinical assessment of peripheral nerve and muscle physiology in the mid-20th century, spawning the neurologic specialty of clinical neurophysiology. Electrodiagnostic signals are now mostly digitized and increasingly computerized. Studies remain indispensable for the proper diagnosis and management of patients with neuromuscular disease. Despite technologic improvements, a basic understanding of the principles, potential errors, and disease-specific effects are essential for meaningful interpretation and conclusions. Notably, these techniques provide physiologic information in contrast and complementary to the primarily anatomic information provided by various imaging technologies. This chapter provides a brief overview of nerve conduction studies (NCS), needle electromyography (EMG), neuromuscular junction assessment, and central motor function techniques.

NERVE CONDUCTION STUDIES

Sensory and Motor Nerve Conduction Studies

The NCS measure the speed and strength of an electrical impulse conducted along a peripheral nerve. Typically, the impulse is generated using a bipolar stimulator placed on the skin surface over the anatomic course of the tested nerve. The intensity and duration of this transcutaneous stimulus is gradually increased until all available axons within that nerve are depolarized, sparking an action potential that travels down the nerve to the recording site. For *sensory NCS*, the recording electrodes are placed on the skin surface overlying the nerve (usually over a pure sensory branch) at some distance from the stimulation site (**Fig. 27.1**).

When an action potential passes under these bipolar recording electrodes, a *sensory nerve action potential* (SNAP) waveform is recorded and displayed (**Fig. 27.2**). The SNAP is produced by large Ia sensory axons and not small-diameter A or C fibers.

Motor NCS are performed similarly, except that the recording electrodes are placed over the motor endplate region of an innervated muscle, rather than over the nerve itself (**Fig. 27.3**).

FIGURE 27.1 Setup for sensory nerve conduction studies. A bipolar stimulator is placed over the median nerve at the wrist, and self-adhesive recording electrodes are placed over the median sensory branches over the index finger, ensuring that only sensory nerve responses are recorded. A self-adhesive ground electrode is placed over the dorsum of the hand.

FIGURE 27.2 Sensory nerve action potential recorded using the setup depicted in **Fig. 27.1**. The horizontal space between two dots, or graticules (one division), is assigned a specific value (the time base shown is 1 ms per division) to enable time measurements. Vertical divisions are also assigned a specific value to enable measurement of stimulus strength (the gain or sensitivity; 10 μV per division as shown). The time between the stimulus artifact and the waveform peak (the sensory peak latency) is 2.75 milliseconds, and the peak-to-peak waveform amplitude is 13.2 μV, within the normal range. Onset latency is needed to calculate a conduction velocity.

For motor NCS, the action potential passes down the nerve, triggers acetylcholine release at the neuromuscular junction, and produces muscle membrane depolarization. The recording electrodes capture the electrical potential generated by depolarization of the innervated muscle, subsequently generating a waveform known as the *compound motor action potential* (CMAP) (Fig. 27.4). Care must be taken to maximally but not excessively stimulate nerve axons at each stimulation site. Multiple other technical considerations can impede quality NCS and must be controlled as much as feasible, including standardized procedures, temperature maintenance, accurate electrode placement and measurement, interference avoidance, detection of anatomic anomalies, and stimulation of unintended nerves.

FIGURE 27.3 Setup for motor nerve conduction studies. The bipolar stimulator is placed over the median nerve at the wrist, and recording electrodes are placed over the median-innervated abductor pollicis brevis. The resultant muscle depolarization produces the recorded waveform. Note that sensitivities are in the millivolt, rather than microvolt, range.

FIGURE 27.4 A compound motor action potential. These three responses were recorded from the extensor digitorum brevis muscle of the foot following stimulation of the peroneal nerve at three different sites: the ankle (**top waveform**), just below the fibular head (**middle waveform**), and above the knee (**bottom waveform**). The recording sensitivity was 5 mV per division, and the sweep speed was 5 milliseconds per division. Onset latencies are 4.0, 11.1, and 13 milliseconds, respectively, predictably increasing as the distance between the stimulating and recording electrodes increases. Subtracting one onset latency from another yields the time for the impulse to travel from one stimulation point to the other. The measured distance is divided by this value to produce the segmental conduction velocity in meters per second. The amplitude is measured from baseline to peak.

Although modern equipment is computerized with digital processing and storage to capture and analyze the data, the waveform display owes its origins to the cathode ray oscilloscope. By convention, the x-axis of the tracing is the time base (or sweep speed) in milliseconds, whereas the y-axis measures the impulse strength. The waveform *amplitude*, measured either in microvolts (sensory waveforms) or millivolts (motor waveforms), reflects the summated number of responsive nerve axons. The time difference between the stimulus and the waveform onset, one of several measures of nerve speed, is the *distal latency*. Using this value and the measured distance between the stimulating and recording points, a *nerve conduction velocity* may be calculated for sensory nerves (m/s). Some prefer to measure the latency to the sensory waveform peak instead of the onset and to compare this

value to controls (*peak latency*). Similarly, the *distal motor latency* is measured from the stimulation point to the waveform onset and compared to control values; some laboratories use a standard distance from the stimulation point and the muscle to improve reliability. Because of the non–nerve-related components of the motor system including the neuromuscular junction and muscle membrane depolarization, motor NCS require additional stimulation sites to calculate conduction velocity. A waveform from a second, typically more proximal, stimulation site is captured and the time difference between the two waveforms is measured. This step subtracts out the time for the nonnerve factors and assesses only the motor nerve axon components. The distance between the two sites (mm) divided by the time difference (ms) provides the *conduction velocity* of that segment (m/s). Additional segments may be added by stimulating further sites along the nerve course. Accuracy is reduced, however, if the stimulation points are too close together. A difference of 10 cm is typical except for special circumstance, such as short-segment studies across the elbow in the assessment of ulnar neuropathy. Another consideration is the accessibility of the nerve to surface stimulation.

It is important to measure and control limb temperature; cold limbs influence many electrodiagnostic measures. The most significant effect is on conduction velocity, with a conduction velocity fall on average of 2 m/s/°C and latency increase of approximately 0.2 ms/°C below ideal, typically 32°C.

Because muscle tissue is much more electrically potent than nerve fibers, the CMAP is approximately three orders of magnitude larger than the SNAP, and its amplitude is measured in millivolts rather than microvolts. Otherwise, latency and amplitude measures are similar to the SNAP.

Both latency and conduction velocity depend on an intact, myelinated nerve; myelin and the saltatory conduction it fosters are essential for rapid action potential propagation. In contrast, the waveform amplitude depends primarily on the number of functioning axons within the nerve. Significant slowing of conduction velocity or prolongation of latency usually implies demyelinating injury, whereas loss of amplitude usually correlates with axonal loss or dysfunction. However, axonal loss also may mildly slow conduction velocity by eliminating the fastest conducting axons. When demyelination is severe enough, a complete block of transmission in most axons can occur; demyelination results in a loss of local current and an insufficient charge to activate the next node of Ranvier. The NCS may be used to demonstrate the conduction block. In this situation, recordings made from nerve stimulation above the site of injury produce waveforms with a much lower amplitude and area than recordings made from stimulation below the site of demyelination of the same nerve. When severe enough, this loss of waveform amplitude due to block of impulse transmission in a group of axons at a single site is known as a *conduction block* and is an important diagnostic feature of acquired demyelinating neuropathies (Fig. 27.5). If some, but not all, fibers show reduced conduction velocity without a conduction block, the increased range of velocities may produce *temporal dispersion*, a broadened waveform that demonstrates increased waveform duration but a lesser reduction in waveform area. Despite the fact that certain accessible nerves dominate most NCS, techniques are described for most recognized peripheral nerves; studies for uncommon procedures are performed on the basis of clinical necessity.

FIGURE 27.5 Conduction block with temporal dispersion. Two compound motor action potentials recorded from the abductor hallucis muscle of the foot following stimulation of the tibial nerve at the ankle and the knee (**top** and **bottom**, respectively) in a patient with demyelinating neuropathy. The sensitivity was 1 μV per division, and the sweep speed was 5 milliseconds per division. When stimulation is moved from the ankle to the knee, the recorded waveform decreases in amplitude (from 1.1-0.5 mV, a 54% decline), its duration lengthens, and its morphology becomes irregular and complex. These findings suggest significant demyelination of the nerve segment between the stimulation sites, with partial conduction block. An increased range of axonal conduction times between different axons, caused by differential involvement, produces increased waveform duration as the distance between stimulation and recording sites increases (*temporal dispersion*). A 30% increase is considered to be significant in motor axons.

Late Responses

Routine NCS are limited to accessible segments in the proximal and distal arms and legs. Nerve roots are not easily stimulated, and *long-latency reflex* tests are typically used to assess these most proximal segments. When a stimulus is delivered to the distal nerve, action potentials are propagated both proximally and distally. The impulse traveling up the motor axons (in a direction opposite to the normal flow or *antidromic*) eventually reaches the anterior horn cells. The anterior horn cells then generate a second nonsynaptic action potential that travels back down the axon into the muscle (in the direction paralleling the normal flow or *orthodromic*), where it is recorded as a much smaller waveform known as the *F wave*, named because it was originally recorded foot muscles (Fig. 27.6).

The time required for this round trip up and down the motor nerve is measured as *the F-wave minimal latency*. Although pathology at any point along the nerve may prolong the F-wave latency, if normal function of the distal nerve is documented by motor NCS in the more distal nerve sites, F-wave prolongation must be the result of slowing in the proximal segment.

A different long-latency response, *the H reflex* (named after Hoffmann, who first described it in 1918), may be elicited in

FIGURE 27.6 A series of F waves recorded from the thenar eminence following repeated median nerve stimulations in a patient with cervical radiculopathy. The screen is split with lower sensitivity (5 mV per division) to the left of the *dotted line* to show the full compound motor action potentials generated by distal stimulation and higher sensitivity (200 µV per division) to the right to allow visualization of the much smaller F-wave responses. The sweep speed is 10 milliseconds per division. The *dark vertical line* marks the latency of the earliest F-wave potential in the group (minimal F latency).

the legs by electrical stimulation of the type Ia sensory nerve afferents in the tibial nerve at the knee while recording over the soleus muscle. (The type Ia sensory fiber [also called the *primary afferent fiber*] is a component of the muscle spindle that monitors stretch velocity.) The contraction resulting from soleus activation is analogous to the monosynaptic stretch reflex pathway elicited by testing the tendon reflex. Thus, the H reflex is the electrical equivalent of the ankle jerk reflex and aids primarily in the assessment of S1 nerve root disease and involvement of sensory fibers. In adults, the H reflex is not normally found in other muscles except for the flexor carpi radialis. F waves are present in nearly all nerves. By analyzing motor and sensory nerve conductions and long-latency responses in multiple nerves, the nature of a given neuronal injury (axonal, demyelinating, or both) and its geographic distribution may be identified, aiding in the diagnosis of neuronopathy, radiculopathy, plexopathy, mononeuropathy, and polyneuropathy.

Other Specialized Reflex Tests

Numerous other reflex tests are described and uncommonly performed. The *blink reflex* is one exception. This relatively simple-to-perform test assesses both trigeminal and facial nerve pathways. Recording electrodes are placed on the orbicularis oculi bilaterally, and the supraorbital nerve is stimulated. An ipsilateral R1 response is seen on the stimulated side only. A later R2 complex response is seen bilaterally. Differing patterns are evident in trigeminal or facial neuropathy and central pontine or medullary disease.

NEEDLE ELECTROMYOGRAPHY

Basic Concepts

Complementary to NCS is assessment of clinically relevant muscles using needle EMG. A sterile, disposable, needle recording electrode is placed directly into the selected muscle, which is then activated by voluntary contraction at differing levels of effort. Anterior horn cell action potentials propagate impulses to the end of multiple axonal branches and initiate neuromuscular junction transmission, thereby activating individual muscle fibers; normally every muscle fiber innervated by a motor neuron fires following a nerve action potential. A single motor axon with all of its multiple branches and innervated muscle fibers is known as a *motor unit*. The strength of a muscle contraction is determined primarily by the number of activated motor units and motor unit firing rates. The recording characteristics of the EMG needle enable live recording and analysis of individual and aggregate motor unit waveforms. Two types of electrode are most commonly used. *Monopolar electrodes* are flexible, solid stainless-steel needles coated with inert material so that only the bare tip can record activity. The reference point is typically a surface electrode on the skin. *Concentric electrodes* are a rigid stainless-steel cannula that includes a specialized central wire. The activity is recorded from the wire and referenced to the cannula. Monopolar needles record from a larger territory, which is slightly better for spontaneous activity discussed later. Concentric electrodes record from a smaller area and are better for motor unit analysis also discussed later. Some consider monopolar electrodes to be less painful, but the difference is minimal when ultrasharp disposable electrodes are used. Either electrode is acceptable for use.

Insertional and Spontaneous Activity

During the needle EMG examination, three major categories are assessed: *spontaneous activity*, *motor unit configuration*, and *motor unit recruitment*, including the *interference pattern*. Different areas of the muscle are explored to ensure a representative sample and to detect focal changes. Insertional activity is the brief burst of electrical activity provoked by the EMG needle as it moves through the muscle, generating a cluster of transient high-frequency spikes lasting from 50 milliseconds to a few hundred milliseconds. In some disorders, the insertional activity is consistently prolonged or reduced with each movement of the needle, but the distinction is often subjective and not considered by most to be diagnostic. Once needle movement has ceased, no other electrical activity should normally appear as long as the muscle remains at rest. Reduced insertional activity is present in muscle replaced by nonexcitable tissue, such as fat or connective tissue.

Muscle fibers that have lost innervation through motor axon injury or muscle degeneration or muscle necrosis may undergo spontaneous depolarization, generating brief spikes (*fibrillations*) and *positive sharp waves* in the resting muscle; sharp waves usually fire in a regular pattern with a frequency of 0.5 to 15 Hz (Fig. 27.7). This activity is generated by individual myocytes. Waveforms similar to fibrillations normally occur at the muscle endplate region and must be distinguished; *endplate spikes* also fire at fast semirhythmic rates. Also recorded at the endplate region is *endplate noise*, a disturbance of the baseline that correlates with miniature endplate potentials.

FIGURE 27.7 Spontaneous activity in a resting muscle. This tracing was recorded from the triceps muscle of a patient with cervical radiculopathy. A positive sharp wave, named for its sharp initial positive (downward) deflection, is seen on the **left**. On the **right**, a smaller triphasic fibrillation is seen. These potentials are markers of active denervation and result from the random, spontaneous depolarization of denervated single muscle fibers.

FIGURE 27.8 A normal MUP. This waveform was recorded from the biceps muscle with a concentric needle electrode as the first potential recruited during minimal voluntary contraction in a normal subject. Sweep speed was 10 milliseconds per division, and sensitivity was 500 μV per division. This waveform has an amplitude of 1.4 mV, a duration of 12.5 milliseconds, and a simple morphology with three turns.

Abnormal spontaneous activity is the hallmark of denervating axonal injury at any point from the anterior horn cell to the nerve terminal (eg, radiculopathy, plexopathy, axonal polyneuropathy, mononeuropathy) but is also prominent in inflammatory myopathies, such as polymyositis or dermatomyositis because of isolation of section of muscle from the endplate region producing functional denervation. Lesser degrees of spontaneous activity may be observed in other myopathies with muscle fiber necrosis (eg, myotonic dystrophy, Duchenne or limb-girdle muscular dystrophy) and in some toxic, metabolic, and infectious myopathies (eg, myoglobinuria [rhabdomyolysis] or viral myositis). Spontaneous activity typically begins to initially occur at 10 to 14 days after denervation but is more evident 3 to 4 weeks after onset and may persist for a protracted time unless that muscle fiber is reinnervated. Cold muscle temperature will reduce evident spontaneous activity.

Other aberrant involuntary discharges may appear with certain neurogenic or myopathic disorders. *Fasciculations* are isolated spontaneous discharges of whole or partial motor units and are prominent in motor neuron disease, benign fasciculation syndrome, and disorders of nerve excitability. Fasciculations may be visible as a muscle twitch, EMG needle sudden movement, or recordable discharge. *Complex repetitive discharges* are relatively nonspecific, machine-like phenomena more common in chronic neurogenic conditions. These discharges are very regular and start and stop abruptly. The origin is considered to a stable circuit created between several adjacent muscle fibers. *Myotonic discharges* are distinctive discharges that resemble a revving motor. This finding has limited associations, including myotonic dystrophy and myotonia congenita; however, acquired conditions can also demonstrate these findings. Waxing and waning frequency and amplitude are characteristic. *Myokymic discharges* are repetitive, grouped, nerve-generated discharges (doublets or multiplets) and occur commonly in the facial muscles from diverse cause but are uncommon in the limbs. Limb myokymic discharges suggest radiation injury, timber rattlesnake venom, or certain channelopathies. The origin is nerve components. Most rare are the very rapid *neuromyotonic discharges*, characteristic of Isaac syndrome or other forms of motor unit hyperactivity.

Motor Unit Configuration

Assessment of the waveform generated by motor unit activation (*the motor unit potential* or MUP) yields important information (Fig. 27.8). The MUP parameters include waveform duration, amplitude, and morphology (number of turns or baseline crossings). Motor unit characteristics are best assessed by capturing MUPs with the aid of a trigger and delay line so that the waveform can be frozen and assessed. The duration is measured from the point where the waveform deviates from the baseline to the point where a stable baseline returns following the waveform. The amplitude is typically measured from the largest waveform-positive and waveform-negative peaks. *Polyphasic* waveforms have five or more phases, determined by the number of times the waveform crosses the baseline plus one. Waveform turns or phase reversals are considered as well. The MUPs that contain more than seven or more turns are considered by some to be *complex MUPs*. Both polyphasic and complex MUPs are indicators of desynchronization seen in all forms of chronic neuromuscular disease that affects neurogenic or myogenic components. Small percentages of these potentials are evident in normal muscle as well, typically less than 12%. Some MUPs include a small additional time-locked component following a return to baseline—a *satellite potential*. Because a muscle may contain hundreds of motor units, the EMG examination must include a representative sample of motor units collected at varying levels of voluntary contraction.

Diseases of the motor nerve and muscle alter these motor unit parameters in characteristic ways. When motor axons fail, the associated muscle fibers lose their innervation. However, branches from surviving motor axons in the same nerve may reinnervate these denervated muscle fibers in a process called *collateral reinnervation*. Over the course of several months, this compensatory repair process gradually expands both the total number of muscle fibers innervated by surviving motor units as well as the geographic territory spanned within the muscle. Reinnervated motor units produce abnormally enlarged MUPs of long duration, high amplitude, and increased complexity, which are markers of chronic neurogenic injury (Fig. 27.9).

In contrast, myopathies destroy or inactivate some muscle fibers in most or all of the motor units within a muscle, thereby reducing both the number and distribution of fibers within each unit, producing abnormally small MUPs of short duration, low amplitude, and increased complexity (Fig. 27.10).

FIGURE 27.9 A neurogenic MUP. This waveform was recorded during voluntary activation of the gastrocnemius muscle with a concentric needle electrode in a patient with a distal diabetic neuropathy. Sweep speed was 5 milliseconds per division, and sensitivity was 1 mV per division. This waveform has a high amplitude of 10 mV and a significantly increased duration of 29 milliseconds and is highly complex, with more than 10 turns. This motor unit likely innervated a number of muscle fibers denervated from loss of other motor axons, producing the characteristic MUP changes in neurogenic conditions.

FIGURE 27.10 A myopathic MUP. This waveform was recorded during voluntary activation of the vastus lateralis muscle with a concentric needle electrode in a patient with polymyositis. Sweep speed was 5 milliseconds per division, and sensitivity was 100 μV per division. This waveform has a low amplitude of 210 μV and a short duration of 7 milliseconds and is complex with eight turns. As individual muscle fibers within a motor unit drop out during myopathic injury, the electric potential generated shrinks proportionately, resulting in decreased MUP amplitude and duration and increasingly complex morphology from reduced synchronization.

In normal individuals as well as patients with neuropathic or myopathic disorders, there is a wide range of sizes of individual MUPs. The size of the motor neuron, motor axon, and corresponding motor unit specifies the available strength, maximal firing rate, and fatigue resistance of that unit. In addition, different muscles may have divergent average motor unit size depending on the muscular function. For example, an extraocular muscle may have relatively few muscle fibers per motor unit to deliver small precise movements in contrast to a proximal hip girdle muscle where high fatigue resistance predominates. Thus, the characteristics of a small number of MUPs are insufficient for a definitive diagnosis. Determining the mean duration of 20 MUPs is one reliable way to separate neuropathic from myopathic disorders. Normal values, generated in Copenhagen, for the mean durations of most muscles in each decade of life were published in 1975 and remain widely used. However, qualitative MUP assessment invokes the same process by assessing a number of different MUPs without quantitative measurement. This assessment requires experience with the process and specific muscle undergoing testing.

Disorders of the neuromuscular junction, as in myasthenia gravis, may also prevent activation of enough fibers, owing to cumulative neuromuscular junction blockade, to produce myopathic-appearing MUPs. Following severe nerve injury, the earliest phases of reinnervation and the latest phases of denervation during neurogenic atrophy may also produce short-duration motor units (*nascent units*) when the initial few muscle fibers are reinnervated.

Recruitment and Interference Patterns

Needle EMG also enables assessment of motor unit recruitment patterns. As a muscle begins to contract at the lowest force levels, the first recruited motor unit begins to fire repeatedly at a specific frequency, usually at a minimum of 4 to 5 Hz. As demand for more strength increases, the firing frequency of the motor unit increases until a second motor unit is recruited. The specific firing frequency of the first recruited motor unit at the moment the second motor unit appears is *the recruitment frequency*. Abnormally high recruitment frequencies appear as motor units are lost, forcing surviving units to fire at faster and faster rates before additional units appear because of reduced numbers of motor units available for recruitment. In contrast, because most motor units are smaller and weaker, owing to loss of muscle fibers, lower recruitment frequencies are seen in myopathies (*early recruitment*). Consequently, multiple motor units must be activated earlier than in normal subjects to generate the same levels of force. Following damage to upper motor neuron pathways, recruitment is disordered, and motor units may fire at a slower than needed rate despite true maximal voluntary effort, as disrupted descending impulses improperly modulate firing frequency. The *firing ratio* is calculated by dividing the firing frequency (firing rate of the fastest firing MUP) over the number of different MUPs activated. This ratio is typically around five. In other words, if the fastest MUP fires at 15 Hz, one expects to see three total firing MUPs. Neurogenic processes increase this ratio.

The *interference pattern* is the overlapping pattern generated by the simultaneous activation of large numbers of MUPs during maximal contraction; the spike density and the amplitude of the summated response (*envelope amplitude*) are assessed. This response typically appears as a dense band of competing waveform activity at slow sweep speeds, which normally obscures the baseline tracing (Fig. 27.11).

FIGURE 27.11 A normal interference pattern. This dense, overlapping group of MUP waveforms was recorded with a concentric needle electrode from the biceps muscle during maximal voluntary contraction in a normal subject. The pattern represents the simultaneous activation of all the functional motor units within that muscle. The sweep speed was 100 milliseconds per division, and the sensitivity was 1 mV per division.

Normal recruitment from low to intermediate to full contraction should produce a full interference pattern with a conical onset, as amplitudes increase progressively with the recruitment of larger and larger motor units to generate increasing force. *Incomplete or reduced interference patterns* (despite maximal contraction) are seen in advanced denervating disorders as more and more motor units drop out, ultimately leaving a *picket-fence* pattern, termed *discrete recruitment* (Fig. 27.12).

Maximal voluntary effort must be elicited before interference patterns are accurately assessed because poor volitional effort also produces an incomplete pattern; weakness due to central motor neuron injury may also result in reduced recruitment. In contrast, full *interference patterns, despite weakness*, occur with myopathic disorders. A full pattern appears almost immediately with minimal effort, owing to the large numbers of weakened motor units that are required to generate low levels of force. This pattern also has low envelope amplitude because the size of the constituent MUPs is reduced. Advanced methods that attempt to minimize the effects of voluntary effort (cloud analysis) are available on most machines but are not routinely applied, partly from limited normative data.

NERVE CONDUCTION STUDIES AND ELECTROMYOGRAPHY APPLICATIONS

A wide range of neuromuscular and central disorders may benefit from electrodiagnosis. Many specific applications are discussed in other sections dedicated to specific conditions. Some common examples include focal mononeuropathy, multifocal neuropathy, axonal and demyelinating polyneuropathy, motor neuronopathy,

FIGURE 27.12 A reduced interference pattern. This pattern of MUP waveforms was recorded with a concentric needle electrode from the biceps muscle of a patient with amyotrophic lateral sclerosis during maximal voluntary contraction. The sweep speed was 100 milliseconds per division and the sensitivity was 2 mV per division. Instead of the normal, dense band of overlapping MUPs observed in the normal subject (see **Fig. 27.11**), a "picket-fence" pattern (*discrete recruitment*) representing the activation of only one rapid firing motor unit emerges because so many motor units have been lost. The MUP amplitude of the most prominent surviving unit is increased (8-10 mV), consistent with collateral reinnervation.

myopathy, myositis, and radiculopathy. A proper electrodiagnostic medicine consultation relies on a targeted clinical assessment so that the study design is focused on the clinical problem at hand and includes assessment of sufficient but not excessive numbers of clinically relevant nerves and muscles. Small-diameter fibers may be assessed by other means, most commonly skin biopsy for determination of epidermal nerve fiber density. Nerves are amenable to ultrasonography; however, this technology is currently considered to be a supplemental adjunct to electrodiagnostic methods described. A guideline found Level A evidence for use of ultrasound in the diagnosis of suspected carpal tunnel syndrome. Magnetic resonance imaging (MRI) of nerve is increasing sophisticated with higher power magnetic fields and improved protocols (MRI neurography). However, imaging of nerve and muscle is also adjunct information that typically identifies potential sites of nerve swelling and muscle signal changes that do not provide information on the disease type or process. Additionally, the MRI sequences and expertise are not widely available. The MRI can identify atrophic muscles. Practice parameters and diagnostic criteria exist for some common conditions, including but not limited to carpal tunnel syndrome, ulnar neuropathy, amyotrophic lateral sclerosis (ALS), chronic inflammatory demyelinating polyneuropathy, polyneuropathy, and others. In nearly all cases, both sensory and motor NCS and needle EMG are performed. Timely reporting of results is required that includes numeric data described earlier and written interpretation of the normality of obtained values. A diagnostic conclusion based on the data acquired is expected. In some cases, guidance on disease severity, time course, and prognosis is possible.

TESTS OF NEUROMUSCULAR TRANSMISSION

Repetitive Nerve Stimulation

Repetitive nerve stimulation (RNS) studies assess neuromuscular transmission using a standard motor nerve conduction setup (see "Nerve Conduction Studies" section) to deliver a series of supramaximal stimulations to a motor nerve at a specific frequency while recording each generated CMAP. A CMAP trains of 4 to 10 waveforms are usually recorded at rates from 2 to 3 Hz (low-frequency stimulation). By convention, the waveforms within each train are displayed horizontally on the same baseline from left to right (Fig. 27.13).

Trains are then evaluated either for decreases in consecutive CMAP size (as assessed by area and amplitude, from the first to a later potential, typically the fourth or fifth, and expressed as percentage decrement) or for increases in size (usually expressed in percentage increments). Most protocols include one baseline train, followed by a brief period of voluntary exercise without stimulation, and then followed by one immediate, postexercise train and several more trains at intervals over the next 1 to 5 minutes. The role of exercise is explained in the following text. For high-frequency stimulation studies, either transcutaneous stimulation at rates of 20 to 50 Hz, or maximal voluntary contraction itself, which provides painless activation of the nerve at similar rates, is used. However, high-frequency RNS studies are quite painful and very infrequently used in clinical practice; scenarios almost exclusively are for presynaptic disorders such as Lambert-Eaton myasthenic syndrome (LEMS), organophosphate poisoning, or botulism (as described later in the chapter and in Chapter 142)

FIGURE 27.13 Repetitive nerve stimulation. A train of 10 compound motor action potentials (CMAPs) recorded from the thenar eminence following repetitive nerve stimulation of the median nerve at a frequency of 3 Hz, arrayed in the order of stimulation (**left** to **right**). Each individual CMAP is normal, and no significant change in CMAP amplitude or area is observed during repetitive stimulation.

Postsynaptic Neuromuscular Junction Dysfunction

Patients with postsynaptic neuromuscular junction dysfunction, most commonly caused by myasthenia gravis, may demonstrate decremental responses following low-frequency stimulation. During normal neuromuscular junction transmission, depolarization of the motor axon induces acetylcholine release from the nerve terminal; the transmitter diffuses across the synaptic cleft to activate a group of acetylcholine receptors on the muscle fiber, each of which generates a local depolarization. These summated depolarizations ultimately reach threshold and generate a muscle action potential, which then initiates muscle fiber contraction. Declining release of acetylcholine normally occurs with stimulation at low frequencies; however, because postsynaptic acetylcholine receptors are abundant, these declines do not affect neuromuscular transmission, ensuring adequate muscle fiber depolarization despite the lower levels of acetylcholine released (*safety margin*). However, in myasthenia and some rare genetic postsynaptic disorders, the decline in acetylcholine release becomes critical because there are fewer functional acetylcholine receptors. The result is failure of neuromuscular transmission at multiple neuromuscular junctions with continued stimulation. As increasing numbers of muscle fibers drop out with successive stimulation, the size of the overall summated CMAP also decreases (Fig. 27.14). Rare hereditary disorders of neuromuscular

FIGURE 27.14 Decrement during repetitive nerve stimulation (RNS). Progressive decreases in the size of compound motor action potentials were recorded from the thenar eminence during a train of RNS at 3 Hz in a patient with myasthenia gravis. Losses in both amplitude and area of 40% to 50% appeared during RNS, owing to transmission failure at increasing numbers of neuromuscular junctions.

junction physiology (congenital myasthenia) cause differing effects on this test depending on the affected component.

Additionally, the size (amplitude or area) of a single CMAP immediately after brief exercise, in myasthenia, may increase by 10% to 50% or more compared to the baseline (preexercise) CMAP. This phenomenon, known as *postexercise facilitation* or *posttetanic potentiation*, is attributed to a temporary increase in acetylcholine release after a brief maximal contraction because of transiently heightened presynaptic calcium influx. Postexercise facilitation is assessed by comparing the first CMAP in the first train acquired immediately after exercise to the amplitude of the first CMAP in the preexercise train. In addition to postexercise facilitation of CMAP amplitude, any decrement in the baseline train may transiently improve immediately after exercise (*decrement repair*). However, after this transient repair, decrement typically worsens in trains recorded over the next 3 to 4 minutes, often dipping below baseline (*postactivation exhaustion*) as reserve acetylcholine levels are exhausted. Decrement ultimately returns to preexercise levels within 10 minutes. The decrement is typically greater in proximal and bulbar muscles but is simpler and more reliably performed in distal muscles. Cold temperature will blunt and warmer temperature will enhance the degree of decremental response.

Presynaptic Neuromuscular Junction Dysfunction

In the presynaptic LEMS and some cases of botulism, the CMAP amplitude may be reduced on routine NCS, and low-frequency RNS produces decrement similar to that seen in postsynaptic dysfunction. Both the low-baseline CMAP and the decrement seen on low-frequency stimulation are the result of the combination of normal decline in acetylcholine release at low rates of stimulation superimposed on the diminished release of acetylcholine resulting from antibody blockade of the presynaptic voltage-gated calcium channel (LEMS) or disruption of the mechanisms of acetylcholine release (botulism). High-frequency RNS, in contrast, characteristically leads to CMAP increment (facilitation) over 1 to 2 seconds, usually exceeding 100%. The pain of high-frequency stimulation may be avoided by having the patient voluntarily contract the muscle with maximum force for 10 to 20 seconds, after which a second single CMAP is immediately obtained; this "exercise test" shows postexercise facilitation comparable in magnitude to the increment observed after high-frequency stimulation.

Single-Fiber Electromyography

Another test of the neuromuscular junction is single-fiber electromyography (SFEMG). A specialized reusable electrode or small concentric disposable electrode is used that records single muscle fiber potentials. When an axon is selectively stimulated and a single muscle fiber action potential is measured (*stimulated SFEMG*), the interval between stimulus and response varies with each stimulus. This normal variation results from the fluctuating time required for electrochemical transmission across the junction and is quantitated as *jitter*. *Volitional SFEMG* recordings are more commonly performed and measure jitter by assessing the differences between two voluntarily activated muscle fibers from the same motor unit. With neuromuscular dysfunction, jitter increases, and, in severe cases, complete block of neuromuscular transmission may be documented. An SFEMG is the single most sensitive assay of neuromuscular junction dysfunction in myasthenia gravis, having a sensitivity of greater than 95% when applied to a clinically affected muscle (Fig. 27.15A,B).

FIGURE 27.15 **A:** Single-fiber electromyography in a normal subject. In this tracing, 50 to 100 consecutive discharges generated by two single muscle fibers from the same motor unit during voluntary activation of the frontalis muscle are superimposed. The tracings are arrayed so that the first (*left*) potential is fixed with each discharge. Consequently, the variability in the time between the firing of the first (*left*) and second (*right*) potential with each discharge (the interpotential interval) is illustrated solely as variation of the second waveform. This effect, quantitated as *jitter*, is due to the variable time required for neuromuscular transmission to produce an action potential from discharge to discharge. **B:** Single-fiber electromyography in a patient with myasthenia gravis during volitional activation of the frontalis muscle using the same recording methods described in **A**. This tracing illustrates increased variability in neuromuscular transmission and clearly differs from that of the normal subject above. The jitter in this fiber pair is 160 microseconds, well above the normal upper limit.

Although SFEMG is highly sensitive, it is not specific and may be abnormal in any condition causing damage to nerve or muscle that produces reinnervation. Consequently, it is essential to perform other electrodiagnostic methods and a careful clinical assessment before considering SFEMG. An SFEMG is most useful for confirming neuromuscular junction dysfunction in suspected myasthenia gravis when other tests are equivocal or negative and other conditions that produce muscle weakness are assessed (see **Fig. 27.11**). Because of the limitations of reusable SFEMG electrodes that require cleaning, sharpening, and sterilization, use of high gauge disposable concentric needles is increasingly popular. These electrodes, however, record a large territory and may underestimate jitter; true single-fiber recordings are more difficult. Use of a higher low frequency filter (1 kHz) and a lower normal range are advised.

TRANSCRANIAL MAGNETIC STIMULATION

Transcranial magnetic stimulation (TMS) evokes compound motor potentials through noninvasive stimulation of the cortex. The TMS is an important method for studying the conductivity and excitability of the corticospinal system, abnormal cortical circuitry in neurologic diseases, and the reorganization of sensorimotor and visual systems after peripheral and central lesions. Electromagnetic induction may stimulate neural tissue. The TMS is accomplished through the generation of high-intensity current (5-10 kA) and discharged as a quick pulse through wire coils placed on the surface of the head. The coils induce a magnetic flux of short duration (100-200 μs) and high intensity (1-2 T). The magnetic fields, in turn, induce electrical current in the underlying cerebral cortex. The TMS delivery devices are embedded in a nonconductive plastic or rubber material and typically fashioned into figure eight, butterfly, or flat or concave circular shapes and applied near the part of the brain under study. The various shapes and sizes are designed to distribute or focus the induced magnetic fields. Round coils generate more diffuse magnetic fields and figure eight coils produce a narrower region of neural activation.

Stimulus intensity is expressed as a function of either the motor threshold or the percentage of machine output. The TMS is less painful than transcranial electrical stimulation, which causes uncomfortable shocks in the underlying skin and muscle. Unlike transcranial electrical stimulation, which directly excites cortical long tracts, the induced electrical fields of TMS preferentially stimulate neural elements oriented parallel to the surface of the brain (ie, primarily interneurons). The TMS pulses are associated with benign acoustic clicks and mild scalp or facial muscle activation. A momentary sense of disorientation at maximal stimulation may be felt. However, there are virtually no clinical cognitive or sensory effects at low intensities of TMS stimulation. Waveform recordings are usually obtained from a contralateral distal limb muscle, the motor-evoked potential (MEP).

A TMS may be delivered as a single pulse, in paired pulses, or as repetitive trains of stimulation (repetitive transcranial magnetic stimulation [rTMS]). Paired pulse and rTMS are powerful in studying human brain function, transiently stimulating or inhibiting different brain areas in awake and behaving subjects. Effects of rTMS on cortical excitability and inhibition outlast (for minutes to hours) the stimulation itself, a characteristic that could lead to therapeutic applications. Clinical trials have been conducted primarily not only in depression but also in Parkinson disease, epilepsy, obsessive-compulsive disorders, and schizophrenia.

Single-Pulse Transcranial Magnetic Stimulation

Following a single TMS, the MEP latency and amplitude measure the integrity of pathways and membrane excitability characteristics of the upper motor neuron. Central motor conduction time is calculated by subtracting the peripheral MEP latency (ie, cervical or lumbosacral proximal roots to distal limb muscles) from the total conduction latency (ie, TMS to MEP onset of the same muscle) and is obtained with a single, maximal TMS over the primary motor cortex (**Fig. 27.16**).

Prolongation of the central motor conduction time may originate with the loss of large myelinated motor axons subsequent to degeneration, and the test assesses upper motor neuron (UMN) dysfunction. Central motor conduction time, as well as other TMS measures, is helpful in diagnosing and following progression in patients with upper motor neuron diseases, such as ALS. However, central motor conduction time may be of limited value when large-diameter axons remain normal or in diseases where long-tract integrity is known to be normal, such as Parkinson disease.

As a measure of UMN functional integrity, TMS may detect abnormalities when there are no clinical UMN signs. The TMS may reveal subtle subclinical UMN dysfunction and help clarify the diagnosis of ALS, as well as the relationship between ALS and its variants, including progressive muscular atrophy where there may be subclinical UMN changes.

The MEP amplitudes and latencies are influenced by multiple factors, including configuration and placement of the TMS coil, stimulus intensity, presence of conditioning pulses, muscle facilitation, and degree of phase cancellation. Suprasegmental modulation of MEPs may be inferred in several ways, including demonstration of relatively unchanged F-wave properties under the same stimulus conditions. Motor threshold is defined as the lowest stimulus intensity that evokes MEPs of 50 μV in amplitude in 5 of 10 trials. Stimulus intensity is expressed as a percentage of the TMS device's maximum output. The MEP amplitude is usually measured peak to peak, increases with stimulus intensity, and plateaus at 80% of the amplitude of the wave produced by peripheral stimulation.

Voluntary muscle activation during TMS lowers the motor threshold and increases the MEP amplitude and is associated with shorter latency. This facilitation may result from an increased number and synchronization of descending impulses from the motor cortex or from reafferent facilitation at the spinal level. Recruitment is measured by plotting a stimulus-response curve of stimulus intensity versus MEP amplitude. The slope of this curve is normally increased by facilitation as well as by maneuvers that enlarge cortical representation of muscles, such as highly skilled, fine motor actions. Temporal summation may also follow repeated delivery of stimuli. In the first minutes following rTMS trains at low frequency (1 Hz), the amplitude of single-pulse MEP decreases. Conversely, high-frequency (>10 Hz) stimulation increases the response; these patterns resemble long-term depression and facilitation.

FIGURE 27.16 Transcranial magnetic stimulation in a normal subject. These tracings show the motor-evoked responses recorded from the right and left abductor digiti minimi (ADM) muscle of the hand and the right and left tibialis anterior (TA) muscles, following stimulation of the cerebral cortex with the stimulator placed over the vertex of the skull (traces *A1* to *A4*) and following stimulation of the spine; cervical stimulation for the ADM and lumbosacral stimulation for the TA is shown in traces *B5* to *B8*. Latencies, in milliseconds, from stimulation to the onset of the waveform recorded from the muscle are shown in the *first column* (*LAT1*). Central-conduction latency (ie, time from cortex to spinal segment) is calculated by subtracting the peripheral-conduction latency (ie, time from spine to muscle) from the total conduction latency (ie, time from cortex to muscle) and is shown in SEGMENT table, final column (DIFF).

Silent Period

The cortical or central silent period is measured from an actively contracting muscle, representing suppression of voluntary EMG activity for up to 300 milliseconds after a single TMS. The cortical silent period is an important method of assessing inhibitory mechanisms in neurologic disease. The silent period typically follows a MEP but may be induced by subthreshold stimuli that do not produce a MEP. This *negative effect* is mechanistically distinct from the positive effect seen in MEP induction. Although the origin of the initial segments of the cortical silent period are controversial, the latter part of the silent period is modulated by central mechanisms.

Repetitive Transcranial Magnetic Stimulation

Technical advances allow rTMS output from just under 1 Hz to pulse trains up to 50 Hz. The rTMS at frequencies greater than 20 Hz increases cerebral blood flow and neuronal excitability, whereas low-frequency rTMS (1-2 Hz) has the opposite effect. The therapeutic potential of TMS is of interest as a painless and relatively safe alternative to electroshock therapy. The TMS is a treatment option in treatment refractory depression and is under study for pain syndromes including migraine, stroke recovery, obesity, refractory schizophrenia, and other neurologic and psychiatric disorders.

Autonomic Testing 28

Louis H. Weimer

KEY POINTS

1. Clinical autonomic testing assess responses of reflex loops instead of direct nerve measures.
2. Testing most commonly measures heart rate variability, blood pressure responses to adrenergic challenges, and sudomotor (sweating) responses.
3. Consensus agreement advised testing a variety of measures.
4. Additional organ-specific testing is often by nonneurology specialists.

INTRODUCTION

Recognition of disorders producing autonomic dysfunction continues to increase the demand for noninvasive clinical testing in order to validate clinical diagnoses. Because autonomic systems affect virtually all organ systems, symptoms produced are multiple and varied, often affecting functions not considered by neurologists. Because many autonomic complaints can appear to be nonspecific, objective assessment is desirable in many instances. Laboratories testing autonomic function are generally available in part due to reliable noninvasive techniques. Formal accredited training opportunities in this neurologic specialty are limited but are available and increasing.

Unlike other systems, autonomic function is not directly assessed. Instead, responses of complex overlapping reflex loops are measured after controlled perturbations, most commonly heart rate (HR), blood pressure (BP), and sweating. Techniques to evaluate autonomic function are numerous and continue to be devised, but only a limited number are considered to be suitable for routine clinical application (**Table 28.1**). Tests of cardiovagal, adrenergic, and sudomotor function are most commonly performed and are recognized, standard clinical measures. Consensus recommends use of a standardized testing battery in a controlled setting. Bedside screening tests complement a clinical evaluation; some techniques can be performed with limited equipment such as an electrocardiography or electromyography machine. The primary testing goal is to identify autonomic failure and to assess and quantify disease severity. In some cases, determining the systems involved, such as parasympathetic, sympathetic, or panautonomic, can refine diagnostic possibilities. In most instances, localization to central, preganglionic, or postganglionic dysfunction is not possible. The effects of medications, environmental conditions, dehydration, and acute illness should be minimized during testing. Selected commonly performed tests are briefly discussed in this chapter.

SELECTED TESTS

Heart Rate Variability

Measures of HR variability are simple to record and are sensitive indicators of parasympathetic function. Cyclic deep breathing at 6 breaths per minute is the best validated stimulus; both afferent and efferent pathways are vagally mediated and blunted by anticholinergic agents. Most commonly, beat-to-beat HR is recorded, and R-R intervals or sequential HR data are measured, and the resultant enhanced sinus arrhythmia is analyzed with one of numerous methods; the test is currently the best cardiovagal measure available. Age-segregated normative ranges are well described. Other parasympathetic cardiovagal tests include measures of HR variability during rest, coughing, diving reflex, standing, squatting, and active lying down. The HR response to Valsalva maneuver (VM) is discussed later. Spectral and frequency HR analysis is an important research tool that has not been adequately validated for routine clinical application, although commercial automated testing devices using these methods are employed typically by nonneurologists and cardiologists.

Sympathetic Measures

The VM is a reliable and reproducible method that provides information for both parasympathetic and sympathetic function if beat-to-beat HR and BP data are recorded. Devices that noninvasively record continuous BP are typically used; multiple machines are commercially available. The subject blows into a closed tube at 40 mm Hg for 15 seconds while HR and BP are recorded. Isolated Valsalva ratio (VR) HR recording requires minimal equipment, but more information is gathered with less chance of misinterpretation if continual BP is recorded. The VM BP waveform is divided into four distinct phases (I-IV). Phases I and III signify nonspecific transmitted pressure and release from the maneuver, which initially causes cardiac output and BP to drop, providing the test stimulus. Normally, peripheral vasoconstriction and increased HR produce partial or full reversal of the BP decline, marking early (BP drop) and late (BP recovery) phase II. After Valsalva ends, the BP slowly overshoots and later returns to baseline (phase IV overshoot). Adrenergic insufficiency causes phase II to progressively deepen or fail to correct. Phase IV may fail to overshoot. Phase II recovery is likely mediated by α-adrenergic stimulation and phase IV by β-adrenergic supported by pharmacologic studies. The HR normally increases during the Valsalva period and then overshoots below baseline values.

The VR is calculated by dividing the R-R interval of the HR nadir over the HR peak. Normative values are well established and decline with age. The baroreflex index is also measurable

TABLE 28.1 Selected Tests of Autonomic Function

Cardiovagal
Well established
HR variability to cyclic deep breathing
HR response to the VM (VR)
HR response to standing (30:15 ratio)
Other
Diving reflex/cold face test
HR variability at rest
HR response to cough
Spectral analysis of HR signals (frequency domain)
Transfer function analysis (nonlinear dynamics)
Adrenergic
Well established
BP response to the VM (phase IV and late phase II)
BP response to orthostatic stress
• Head-up tilt
• Standing
Other
Sustained handgrip test
Squat test
BP response to alternate stressors
• Lower body negative pressure
• Neck suction
• Lying down
• Liquid meal
Plasma catecholamine levels (supine/standing)
Microneurography
Mental stress tests
Cold pressor test
Spectral and transfer function BP analysis
Sudomotor
Well established
Sympathetic skin response
Quantitative sudomotor axon reflex test
Thermoregulatory sweat test
Silastic sweat imprint testing
Skin biopsy for sweat gland innervation
Sudoscan
Additional or investigational methods
Pharmacologic challenges
Vasomotor testing
Pupillary testing (pharmacologic)
Pupillometry, pupillography
Urodynamics/cystometrogram with bethanechol
GI motility studies
GI manometry
Salivary testing/Schirmer test
Penile plethysmography, papaverine injection
Neuroendocrine tests
Neurogenic flare test
Quantitative direct and indirect test of sudomotor function
Cardiac PET scanning

Abbreviations: BP, blood pressure; GI, gastrointestinal; HR, heart rate; PET, positron emission tomography; VM, Valsalva maneuver; VR, Valsalva ratio.

and correlates well with traditional invasive methods. The HR response is affected by both atropine and β-blockade. The isolated HR response can be measured on most current electromyography devices. Abnormalities are evident in a high percentage of patients with autonomic failure and significant autonomic neuropathy; the BP findings are more sensitive than tilt studies, which are described later. Abnormalities also correlate with the severity of diabetic autonomic neuropathy and diabetes disease duration. Patients with orthostatic intolerance or the *postural orthostatic tachycardia syndrome* may show excessive phase II decline and insufficient recovery but additionally markedly enhanced phase IV overshoot and a high VR.

Standing and the 30:15 Ratio

Standing initiates a coordinated sequence of reflexes to maintain BP and therefore cerebral perfusion. Simple HR and BP responses to standing are important bedside markers of autonomic integrity, but further information is gained by laboratory testing. Most labs, however, use passive tilting. Responses are best measured after a supine rest period of 15 to 30 minutes, but shorter periods suffice. Baseline values are recorded, and readings are taken at least every minute for 2 to 5 minutes. Leg muscle contraction necessary for active standing triggers an exercise reflex that transiently reduces BP that can mimic orthostatic hypotension. Pressure normally returns to baseline levels within 1 to 2 minutes but can be delayed for 3 to 15 minutes in patients with mild orthostatic intolerance. This phenomenon is why standing BP measures must be delayed. The 30:15 ratio, the R-R interval ratio of the HR nadir around beat 30 after standing divided by the HR peak near beat 15, is reduced by inadequate parasympathetic function. A BP decrease of 20 mm Hg systolic or 10 mm Hg diastolic within 3 minutes is considered significant; triggered symptoms are also noted. The recognition of delayed or slowly declining BP has been noted that can be missed by shorter measurement periods. Fifteen percent of cases in one series had BP declines between 3 and 10 minutes after head-up tilt, and nearly 40% occurred after 10 minutes suggesting milder adrenergic insufficiency than patients with more acute declines.

Tilt Table Studies

Orthostatic challenge with passive upright tilting is the standard method used in most laboratories. Tilting employs slightly different physiologic mechanisms to active standing; however, testing is more easily controllable, enables reproducible tilting angles, simplifies BP monitoring at heart level, and is easier for patients with neurologic impairment. Neurogenic orthostatic hypotension from autonomic failure or HR changes characteristic of primary orthostatic intolerance are generally evident within

the first 5 to 15 minutes of tilting. In contrast, prolonged studies are often needed to trigger reflex or vasovagal syncope, which are further delayed or require pharmacologic challenge. Tilt angles range from 60 to 90 degrees depending on the laboratory (**Fig. 28.1**). Electrocardiography recordings are continuously monitored, and serial BP measurements are recorded with a manual cuff with an automated sphygmomanometer or ideally with continuous BP monitoring. Additional systems can be simultaneously monitored in special circumstances such as electroencephalography, transcranial Doppler, or noninvasive cardiac impedance plethysmography. The BP measurement point is maintained at heart level. Orthostatic hypotension, however, is a sign and not a disease; diagnosis of central autonomic disorders or autonomic neuropathy also depends on clinical assessment and other autonomic tests (see Chapter 116). Similar to active standing, a systolic BP decline of 20 mm Hg is considered to be abnormal, but most centers require at least a 30 mm Hg drop. Although drops of this magnitude may be asymptomatic, ideally, the patient's typical symptoms are reproduced during testing. Diastolic BP declines of 10 mm Hg are significant.

Patients with autonomic failure often have impaired HR response despite orthostatic hypotension. In contrast, orthostatic intolerance (postural orthostatic tachycardia syndrome) patients have excessive HR increases commonly defined as a 30-beat-per-minute increase usually with a rate exceeding 120 beats per minute and induced symptoms. Asymptomatic orthostatic hypotension is prevalent, especially in elderly patients. Confirmation of benign, recurrent vasovagal syncope, which comprises the majority of unexplained recurrent syncopal cases, is the most frequent use of cardiologic tilt table testing. Unexplained noncardiac syncope is increasingly recognized in older patients, including reflex or situational triggers, carotid sinus hypersensitivity, and acute events with subclinical autonomic failure.

Multiple other techniques that test adrenergic responses have been devised but are considered archaic or research methods because of lower sensitivity or reliability. Orthostatic stress can be enhanced by lower body negative-pressure chambers but primarily only in research applications. The *sustained handgrip test* is performed by continual handgrip at 30% of maximal strength, which normally elevates diastolic BP by at least 10 to 15 mm Hg within 3 to 5 minutes; some normal controls, however, have minimal BP elevation. *Mental stress* is an older method to elevate BP that has unclear use. The *cold pressor test* is another long-standing means to elevate BP that is surprisingly still performed. The subject immerses a hand into ice water for 3 to 5 minutes and BP increases similar to the handgrip test are produced. Measurement of supine and standing *plasma norepinephrine* and other catecholamine levels is a somewhat useful but relatively insensitive marker of adrenergic function. In this circumstance, supine pressure levels characteristically are low and fail to increase adequately with upright tilting. Levels increase poorly with both central and peripheral causes of autonomic failure and rise excessively in pheochromocytoma and some forms of orthostatic intolerance. Nearly unrecordable norepinephrine and epinephrine and increased dopamine levels are characteristic of dopamine β-hydroxylase deficiency. *Microneurography* directly records sympathetic nerve traffic; insertion of a tungsten microelectrode directly into a nerve fascicle enables recording bursts of muscle or skin sympathetic impulses. This powerful technique has important research applications but has limited clinical use and requires considerable expertise and specialized equipment.

Tests of Sudomotor Function

Heat and cold intolerance are prevalent symptoms. Thermal homeostasis is a complex process that relies on both sweating and vasomotor control for heat elimination and shivering and nonshivering mechanisms for heat production and conservation. Disorders producing excessive sweating, with or without neurologic dysfunction, are generally treated by other specialties, usually dermatologists. Vasomotor assessment is possible using laser Doppler techniques but is not highly reliable; however, measurement of sweat gland activity and assessment of sweat gland innervation are commonly performed methods. Reproducible and generally accepted tests are discussed in this chapter.

The *quantitative sudomotor axon reflex test* records chemically induced dynamic sweat output. The test basis is an axon reflex induced by chemically stimulating muscarinic eccrine sweat gland receptors with iontophoresed acetylcholine. This activation induces an antidromic response up a cholinergic axon and induces an orthodromic signal down to a different and isolated group of sweat glands. The sweat produced in this isolated chamber is measured over time. Denervated sweat glands fail to function. Testing requires specialized but commercially available equipment, is reproducible, and correlates variably with epidermal nerve fiber density skin biopsy analysis as a measure of small-diameter nerve integrity. Many, but not most, centers have the necessary equipment. The *thermoregulatory sweat test* assesses sweat output over the anterior body surface in response to a thermal stimulus. This approach uses a physiologic stimulus (core temperature increase) and simultaneously assesses wide areas of skin. An indicator dye, usually alizarin red and not iodine, is applied. The subject is heated to a predetermined degree in a temperature-controlled chamber, and the color change is recorded. Abnormal patterns are readily apparent, but normal variant patterns can complicate interpretation. The test has limited availability. *Sweat imprint techniques* are additional sudomotor testing methods that rely on inducing sweat using heat or cholinergic agents and recording the resultant output on a recording medium; a special quick-hardening silastic media is

typical. Availability of this method is limited. The *sympathetic skin response* is a simple to record and widely available technique well known for over a hundred years. The response, however, is a highly complex multisynaptic reflex with sudomotor activity as the final efferent arm. Both sweat glands and surrounding skin tissue provide the response generators. Interest stems primarily from the simplicity of recording and lack of need for specialized equipment. Multiple protocols are used with various methods. Electrical shock is the most common stimulus; other triggers include startle, cough, deep inspiration, and magnetic stimulation. Responses are best recorded over the palm and sole, ideally all four limbs simultaneously. The evoked amplitude is the most sensitive indicator but is variable and habituates with repeated trials. The range of reported normal values is correspondingly wide; no uniform methods or consensus normative values are accepted. Numerous pitfalls hamper meaningful sympathetic skin response interpretation, so the test is not recommended in isolation. Anticholinergic medications dampen responses. Sensory deficits such as sensory neuropathy may blunt the noxious effect of electrical, but not respiratory, stimuli. Anxiety and distractions can produce unprovoked responses.

In addition to epidermal nerve fiber density determination, some skin biopsy samples include sweat glands. The innervating nerves can be stained with PGP9.5 identically to small sensory nerve fibers. New methods to estimate the density of innervation in these complex structures were devised and are commercially employed and available. Measures reliably distinguish patients with diabetic neuropathy from controls. Reduced sweat gland innervation also correlated with thermoregulatory sweat test measures in one cohort of 10 patients. Other techniques to measure or image small nerve fibers are evolving. *Sudoscan* is a newer, emerging, and U.S. Food and Drug Administration–approved technology that measures electrochemical skin conductance that is proposed to correlate with the number of functional sweat glands. Various comparison studies suggest that results correlate with skin biopsy, autonomic symptom and testing quantitative scores, and other measures of small-fiber and autonomic neuropathy.

Other Organ/System-Specific Tests

Multiple other systems are testable. Some measures are less reliable, difficult to perform, require special expertise, or need further evaluation. Some are performed by specialists in other fields, such as pupillography, gastrointestinal motility and manometry studies, cystometry and urodynamic studies, and sexual dysfunction testing.

USE IN CLINICAL PRACTICE

Current autonomic testing batteries have multiple well-validated, sensitive, and noninvasive tests available that can help confirm, quantify, and characterize clinical autonomic disorders. A multispecialty consensus panel in 2009 recommended that there is level B evidence of autonomic testing to be considered as part of a neuropathy evaluation, especially in the setting of suspected autonomic involvement and there is level C evidence for testing patients with purely sensory neuropathy. Autonomic testing is also potentially useful in the assessment of parkinsonian syndromes, multiple system atrophy, acute and chronic autonomic neuropathy, atypical syncope, and other disorders with suspected autonomic insufficiency or autonomic dysregulation. Multiple clinical syndromes can benefit from testing to guide symptomatic and disease-specific therapy and to aid with diagnosis and management.

29 Evaluation of the Special Senses (Vision, Hearing, Smell, Vestibular System)

J. Kirk Roberts

KEY POINTS

1. Diagnostic testing supplements the history and physical examination and is available for all the special senses.
2. Vision testing includes assessment of acuity, color, visual fields, and retinal anatomy and function.
3. Hearing assessments include audiogram and brainstem auditory-evoked potentials.
4. Smell assessments include both informal and formal testing for detection of individual smells as well as smell thresholds.
5. Vestibular function is assessed by electronystagmography/videonystagmography, rotary chair, vestibular-evoked myogenic potentials, and computerized dynamic posturography, along with gait analysis.
6. The sensitivity, accuracy, and limitations of the various diagnostic tests must be understood to properly determine when appropriate to order them as well as in interpretation.

INTRODUCTION

As with all neurologic complaints, diagnosis begins with a proper history and physical examination.

Appropriate testing supplements the examination and provides more refined measures of neurologic function and impairment. The neurologist may order or request testing that is performed by another physician or a technician in another specialty, or the neurologist may supervise, interpret, or perform the test. In either circumstance, the neurologist should understand the test and its appropriate use. This section reviews some commonly performed vision, hearing, smell, taste, and vestibular tests.

VISION TESTING

Visual Acuity

Visual acuity measures central or foveal vision. Testing usually involves reading letters of different sizes but may involve identifying other symbols. The Snellen chart, which uses letters, and the E chart, which uses the letter E in various orientations, are commonly used tests (Fig. 29.1). Testing is typically done at a distance, to approximate infinity, often 20 ft, and the smallest row read accurately is the visual acuity. If distance vision cannot be performed, then near vision may be tested at a distance of 15.7 inches. For those with such poor vision that the largest letter on the eye chart cannot be read, acuity can be recorded, in order of worsening vision by counting fingers, hand motion, and finally light perception or no light perception. So-called normal vision using the foot as the unit of measurement is defined as 20/20 and means the person can see detail at 20 ft that a person with normal eyesight would see at 20 ft. Thus, a person with 20/40 vision can see at 20 ft what a person with normal vision would see at 40 ft. In the metric system, normal visual acuity is reported as 6/6 (meters), and in the decimal system, normal eyesight is reported as 1.00. However, many have vision that is better than 20/20. Moreover, distance vision and near vision acuity may differ because of hyperopia, myopia, or presbyopia. Specialized testing has been developed to evaluate visual acuity in infants, preverbal children, and others who cannot identify the letters or symbols.

Color Vision

Color vision testing is most commonly evaluated with Ishihara plates, many of which have been adapted to handheld devices. This test consists of a series of plates with colored dots with a pattern of different colored dots forming a number or a shape. This test was originally designed to test for congenital disease, which is

FIGURE 29.1 Snellen chart.

most commonly red-green color deficiency. There are other tests of color vision that include blue-yellow testing. Congenital color vision deficiency is not rare and is more common in men than women. Acquired color vision deficiencies typically, although not strictly, divide into loss of red-green vision in optic nerve disorders and blue-yellow vision in retinal or macular disorders.

Visual-Evoked Potentials

Visual-evoked potentials (VEPs), also known as *visual-evoked responses*, are recorded by measuring brain electrical activity over the occipital lobe in response to repetitive visual stimulation (see Chapter 26). Typically, the P100 wave is the most useful response, and its latency and amplitude are measured. Responses, including latency and amplitude, are measured for each eye, with latency prolongation having the most clinical significance. Ocular, retinal, and visual pathway dysfunction may affect the VEP responses. For the neurologist, the VEP is most commonly used in the evaluation of optic neuritis, where there is a prolonged latency from one eye and/or an elevated interocular latency, as long as ocular and retinal pathology has been excluded.

Electroretinogram

The flash electroretinogram tests retinal function and is not affected by damage more central, such as in the optic nerve.

Visual Fields

Visual field testing is commonly performed in the neurologist's office using finger motion and finger counting (see Chapter 4). More formal testing such as Goldman kinetic perimetry uses a test light of various sizes and intensities, which is moved from the periphery to the center of the vision and thus establishes a boundary of visual detection for each level of stimulus. Most visual field testing is now automated (eg, Humphrey) with lights of varying intensities and sizes appearing in different areas of the visual field while the patient's eye is focused on a specific spot (Fig. 29.2). Although the ophthalmologist uses visual fields to monitor a variety of eye conditions, the neurologist is generally monitoring them in patients with occipital lesions or pituitary lesions with pressure on the optic nerve or chiasm.

Optical Coherence Tomography

Optical coherence tomography is a recently developed test that uses light scattering to produce cross-sectional images of the retina with a resolution that allows evaluation of the different layers. It has had increasing adoption in ophthalmologic practices, where it is used in early detection and monitoring of macular degeneration and glaucoma, among other applications (Fig. 29.3). It has been used in neurologic contexts to measure the retinal nerve fiber layer, which reflects the state of the optic nerve. It is reduced, for example, in patients with multiple sclerosis with optic neuritis. Research applications are being explored in a host of neurologic disorders in hopes of identifying biomarkers of potential use in diagnosis or prognostication.

Adaptive Optics

High-resolution retinal imaging is possible with adaptive optics. These systems compensate for optical faults with a wavefront sensor, deformable mirror, and control system and has been used with retinal cameras, optical coherence tomography, and scanning laser ophthalmoscopes. Highly detailed retinal imaging can offer near cellular level detail.

FIGURE 29.2 Computerized automated visual field report showing a right homonymous hemianopia.

FIGURE 29.3 Optical coherence tomography, focusing on retinal nerve fiber layer (RNFL) of an asymptomatic patient presenting to an ophthalmologist for visual health screening. Retinal fields: INF, inferior; NAS, nasal; OD, right eye; OS, left eye; SUP, superior; TEMP, temporal. Images at left are the right retina; images on right are the left retina. This person has less than 1% retinal fiber layer thickness in the right eye in the superior quadrant, more specifically corresponding to about 1 to 2 o'clock. The thickness of other retinal layers are not described but can be separately determined using OCT.

HEARING TESTING

Audiogram

The audiogram or pure tone testing plots the threshold of hearing in decibels (dB) with standardized frequencies, typically from 125 to 8 kHz. Normal hearing is typically better than 15 dB. Each ear is tested, and both air and bone conduction hearing may be tested. Speech audiometry evaluates how softly someone is able hear words and to understand them. Impedance audiometry includes tympanometry, which measures the changes in acoustic impedance with changes in air pressure and basically measures the compliance of the eardrum.

Brainstem Auditory-Evoked Potentials

Brainstem auditory-evoked potentials, also known as *brainstem auditory-evoked responses* or *auditory brainstem responses*, are the auditory equivalent of the VEP (see Chapter 26). In this test, the patient listens to auditory clicks, and electrical responses are generated at specific anatomic points along the auditory pathway: wave I at the cochlear nerve, wave III at the superior olivary nucleus, and wave V at the inferior colliculi. Brainstem auditory-evoked potentials were typically used in the diagnosis of multiple sclerosis and in the evaluation for an acoustic neuroma, but magnetic resonance imaging has largely supplanted this testing. Electrocochleography is another evoked potential measuring the electrical response of the cochlea to sound. It is used to aid in the diagnosis of Ménière syndrome and in perilymph fistula, although its use is controversial. Otoacoustic emissions measure sounds produced by the ear and are useful in that, if present, indicate a relatively normal functioning cochlea with at least near-normal hearing. However, they are not that helpful in determining the cause of hearing loss.

Smell and Taste Testing

Informal bedside testing of smell can be done with nonirritative substances such as coffee or vanilla. Similarly, bedside testing of taste can be done with a salt or sugar solution. Several formal tests are available to evaluate smell and taste, although are more frequently used in research than in clinical practice. One test, the University of Pennsylvania Smell Identification Test consists of 40 microencapsulated odorants in "scratch and sniff" strips. Others are available, which may additionally allow for discretion of smell intensity thresholds as well as individual smells. Relatedly, kits are available to test taste.

VESTIBULAR SYSTEM

Electronystagmography/ Videonystagmography

Electronystagmography (ENG), which uses electrodes to record eye movements, has largely been supplanted in clinical practice by videonystagmography, in which goggles with infrared cameras are used to track eye motion (Fig. 29.4). The test can be divided into three components: ocular motor testing, tests for spontaneous and positional nystagmus, and caloric testing. Ocular motor testing measures several parameters of saccadic motion (the rapid movement of an eye between fixation points) including velocity, accuracy, and latency; smooth pursuit gain

FIGURE 29.4 Videonystagmography.

(the accuracy of following a moving object); and optokinetic nystagmus (the accuracy of following a moving object and the rapid return of the eyes to the original position). The second part includes an evaluation for spontaneous nystagmus with and without fixation. Positional testing includes the Dix-Hallpike maneuver (see Chapter 5) and lateral head and body turn looking for nystagmus associated with canalolithiasis or cupulolithiasis in the posterior, lateral, or anterior canal. Lastly, bithermal caloric testing with both cool and warm stimuli applied to each ear, is completed to evaluate the response of the vestibular system. Conventionally, water irrigation is used, but more and more are using air because of the ease of performing. The vestibular system generates the slow phase, and the velocity of the slow phase is measured in degrees per second, and the responses between the two ears are compared. More specifically, Jongkees formula is used to calculate a relative vestibular reduction by subtracting the sum of the left cool and left warm response from the sum of the right cool and right warm response and then dividing by the sum of all four responses. More than 20% to 25% asymmetry is considered abnormal. Bilateral dysfunction can be suggested by markedly reduced responses (sum total responses <20° per second), but this might also be due to anatomic or technical issues. The use of air, which is potentially less stimulating than water, is of particular concern in this setting. ENG is most helpful at identifying certain peripheral causes of vertigo including benign paroxysmal positional vertigo where there is an abnormal Dix-Hallpike maneuver and unilateral vestibular neuritis where caloric testing is asymmetric. Testing is often normal in central cause of vertigo, but there may be abnormalities in ocular motor testing.

Rotary Chair

Rotary chair testing adds additional certainty to vestibular testing particularly if the ENG is inconclusive and most importantly if bilateral vestibular dysfunction might be present. The rotary chair may also be useful if mechanical obstruction of the ear canal impedes ENG bithermal caloric testing. As it sounds, in this test, a patient is rotated while eye movements are recorded. The chair is moved either sinusoidally or with step changes in velocity, and eye movements are recorded for gain, phase, and

symmetry. Responses to optokinetic stimulation and a test of visual fixation suppression are also measured. In a patient with bilateral vestibular dysfunction, for example, gain is reduced, and there is a phase lead. Although patients with unilateral vestibular dysfunction may also show abnormalities of gain and phase, rotary chair testing is not sensitive to the side of the dysfunction.

VIDEO HEAD IMPULSE TESTING

Head impulse testing is commonly performed at the bedside, where the patient is asked to focus on the examiner's nose and the examiner quickly rotates the head a small amount and looks for a "lag" where the eyes do not stay focused on the nose, but rather travel with the head and there is a late saccade to refixate on the nose. This identifies a peripheral vestibular hypofunction. Video head impulse testing systems using lightweight goggles have now been developed to further quantify and identify vestibular hypofunction, perhaps increasing the sensitivity and accuracy over that of standard bedside testing.

Vestibular-Evoked Myogenic Potentials

Vestibular-evoked myogenic potentials (VEMPs) are a relatively less commonly used test meant to evaluate the saccule and the inferior vestibular nerve. In this test, the response of the sternocleidomastoid to auditory stimuli is recorded. Of note, hearing does not seem necessary for VEMPs. In general, VEMPs are considered abnormal if there is a significant asymmetry or if they are low or absent. In addition, thresholds to generate VEMPs may be abnormally low in patients with perilymphatic fistula or superior canal dehiscence. Some have reported that VEMPs are low or have a higher threshold in Ménière syndrome, but their use in diagnosing this disorder is questionable. Similar responses may also be seen in muscles other than the sternocleidomastoid, such as the eye muscles.

Computerized Dynamic Posturography

Computerized dynamic posturography attempts to quantify balance disorders. In this test, the patient stands on a horizontal platform, which can translate or incline, along with measuring the forces exerted by the patient's feet, and can also alter the visual surround. Testing systems that do not include all of the mentioned are less useful. A common testing protocol includes the sensory organization test, which includes six subtests. The subtests grow progressively more difficult by altering the conditions including eyes open or closed, flat or tilted floor, and vertical or tilted visual surround. Computerized dynamic posturography is not necessarily abnormal in those with vestibular disorders and is therefore complementary to vestibular testing.

Gait Analysis

Gait testing can be formally analyzed through objective metrics, but may be limited to use in specialized centers or research programs, and is discussed further in Chapter 15.

Sleep Studies 30

Andrew J. Westwood and Carl W. Bazil

KEY POINTS

1. A sleep diary is a simple method to obtain information about an individual's sleep over several weeks, particularly in evaluation of circadian disorders and insomnia and to rule out insufficient sleep.
2. Polysomnography is the gold standard diagnostic test of most sleep disorders.
3. Home sleep apnea testing is a convenient screening test for individuals suspected of having obstructive sleep apnea.
4. When narcolepsy is suspected, a polysomnogram followed by multiple sleep latency test should be ordered. A mean sleep latency of less than 8 minutes and two or more sleep-onset rapid eye movement periods is supportive of the diagnosis.

INTRODUCTION

The National Institutes of Health estimates that 50 to 70 million Americans are affected by sleep problems (see Chapter 118). Sleep deprivation and disorders have been linked not only to chronic medical diseases such as obesity, stroke, and diabetes but also to mental health issues and to an increased risk of accidents, particularly motor vehicle accidents. Lack of sleep is not a trivial concern, and increasingly, this is becoming identified by providers and the public.

Validated questionnaires and sleep logs (including those now available as smartphone applications) provide detailed, albeit subjective, information about sleep that can be combined with objective testing to direct appropriate treatment and management of sleep concerns.

INDICATIONS FOR DIAGNOSTIC SLEEP TESTING

The polysomnogram (PSG) is the most common test ordered; however, with changes in medical insurance, many screening home sleep apnea tests are performed prior to this. As well as the overnight PSG, other procedures include the multiple sleep latency test (MSLT), a measure of the ability to fall asleep during the day and maintenance of wakefulness test (MWT), a measure of the ability to stay awake during the day. Additionally, actigraphy—using movement as a surrogate for sleep—can provide useful information about sleep patterns over days to weeks. Each of these will be discussed in detail in the following text.

Polysomnography should be considered for those whose sleep is chronically interrupted, terminates early, or is prolonged in duration. It is not typically useful in those with difficulty initiating sleep unless the individual has not responded well to standard treatments.

Obstructive sleep apnea (compromise of the upper air resulting in disrupted respiration during sleep) is the most common reason for testing due to its high prevalence and ability to mimic other sleep disorders. Symptoms of obstructive sleep apnea may include snoring, frequent nocturia, sensation of choking, or inability to breathe as well as excessive daytime sleepiness, morning headaches, and impaired vigilance in the daytime. Less common symptoms include dream enactment, automatic sleep behaviors, nocturnal limb movements, and nightmares. Signs to suggest sleep apnea include obesity, retrognathia, a crowded oropharynx, and floppy eyelids. Obstructive sleep apnea is common in neuromuscular disorders, cerebrovascular disease, and cognitive disorders. Central sleep apnea (dysregulated respiratory drive in the brain resulting in disrupted respiration during sleep) can be due to Arnold-Chiari malformation, cerebrovascular disease, and cardiomyopathy, for example.

In individuals where prolonged sleep or unexplained excessive daytime sleepiness occurs, the PSG is followed by the MSLT. A very short sleep latency and presence of rapid eye movement (REM) in two or more naps is highly suggestive of narcolepsy. However, recent evidence suggests the repeatability of this test is poor and remains an area of research to provide alternative approaches.

Parasomnias may sometimes be diagnosed entirely by history and without testing, but due to the possible confusion between them, association with other sleep disorders such as obstructive sleep apnea, and mimickers such as nocturnal seizures, polysomnography is often advisable. Parasomnias include night terrors, rhythmic movement disorder, sleepwalking (especially in adults), and REM behavior disorder. When nocturnal seizures are in the differential, polysomnography should be performed with simultaneous video electroencephalography (EEG).

Polysomnography

The (in-laboratory) PSG is the gold standard diagnostic test of most sleep disorders (**Table 30.1**). Clinical polysomnography consists of the simultaneous recording of multiple physiologic variables, allowing objective documentation of sleep state and for evaluation of common sleep disorders. Practitioners will routinely use a minimum of four EEG channels, covering the occipital and central regions required for scoring of sleep, but most will use more. Electrooculography (EOG); mentalis electromyography (EMG); surface EMG of the anterior tibial muscles for detection of leg movements in sleep; electrocardiography; and measurement of nasal and oral airflow, respiratory effort, and oxygen saturation as well as audio and video recording are also standard. Additional variables analyzed may include carbon dioxide monitoring and esophageal manometry.

TABLE 30.1 Indications for Polysomnography[a]

• Diagnosis of sleep-related breathing disorders
• PAP titrations for sleep-related breathing disorders
• Preoperative evaluation prior to upper airway surgery for snoring or obstructive sleep apnea
• Follow-up after good clinical response to oral appliance treatment
• Follow-up after surgical treatment
• Recurrence of symptoms despite initial response to surgical or dental treatments
• Follow-up in patients with substantial weight loss after PAP initiation
• Follow-up in patients with substantial weight gain after PAP initiation
• Insufficient response to PAP therapy despite a good initial response
• Patients with systolic or diastolic heart failure with sleep complaints despite optimal cardiac treatments
• Patients with neuromuscular disorders and sleep complaints despite optimal sleep hygiene
• Narcolepsy (followed by MSLT)
• Periodic limb movement disorder
• Uncertainty of restless legs syndrome

Abbreviations: MSLT, multiple sleep latency test; PAP, positive airway pressure.

[a]Based on Kushida CA, Littner MR, Morgenthaler T, et al. Practice parameters for the indications for polysomnography and related procedures: an update for 2005. *Sleep*. 2005;28(4):499-521.

The recordings are analyzed at 30-second intervals or epochs. Each epoch is evaluated based on muscle tone, electrooculography, and EEG to determine sleep stage or wakefulness. Each epoch is also evaluated for abnormalities in respiratory flow/pressure, oxygen saturation, heart rate, and leg movements (Fig. 30.1). The American Academy of Sleep Medicine provides guidance on scoring for sleep stage and respiratory disturbances (apneas, hypopneas, respiratory-related arousals) as well as limb movements. Once each epoch has been analyzed, a convenient way to display this significant amount of data is the hypnogram. This can show the macroarchitecture over the course of the entire night and can be modified to provide additional information such as timings of respiratory disturbances and body position.

Patients should ideally fill out sleep logs for at least 1 week prior to the test. Medications and napping on the day of the study should be noted, and it is often helpful to have the patient's impression of his or her sleep during the study. It is common for an individual to sleep more supine in the study than at home and should be considered in the clinical implications of the result.

Evoking Parasomnias

Parasomnias such as sleepwalking and sleep terrors typically arise from slow-wave sleep (stage N3). They may not occur on a nightly basis. In order to increase the yield of recording such events, a patient may sometimes be asked to restrict his or her sleep the night prior in order to provoke a rebound of slow-wave sleep. There are some data that deliberate external stimuli, such as sound, during slow-wave sleep may also cause provocation of the events.

Evaluating Rapid Eye Movement Behavior Disorder

Recording of dream enactment behavior during REM sleep (Fig. 30.2) is helpful, however not required, to support a diagnosis of REM behavior disorder. One of the cardinal features of this disorder is the lack of atonia during REM sleep. Atonia is usually identified in the chin lead; however, it may be present in one or more limb leads. Some practitioners may apply additional leads to all four extremities in cases where REM behavior disorder is a concern. It is important to note that melatonin can suppress the atonia and should be stopped prior to the study.

Home Sleep Apnea Test

Obstructive sleep apnea is a prevalent condition within the general population. In those with no significant comorbidities such as neuromuscular weakness, heart failure, seizure disorder, or morbid obesity, a simplified version of the in-laboratory PSG may be warranted. There are many devices available that may monitor only three variables (typically oxygen saturation, pulse, and air flow) or provide a more thorough evaluation including electrocardiography and extrapolated EEG using one or two electrodes. The benefits of the test are typically in cost saving as well as being beneficial for individuals who may not sleep well in unfamiliar environment. As portable testing typically does not allow reliable sleep scoring and excludes video and limb EMG, it is not indicated for evaluation of suspected parasomnias, REM behavior disorder, or periodic limb movement disorder. However, this testing is becoming increasingly required prior to performing in-laboratory polysomnography from insurance companies despite these reservations.

The home sleep apnea test can be a useful screening tool for obstructive sleep apnea but lacks sensitivity, as it yields limited data in many cases, relying on the individual to set up and adjust the equipment. In-laboratory polysomnography may be required if the study remains unrevealing or if the apnea-hypopnea index is borderline.

Multiple Sleep Latency Test

Patients with excessive daytime sleepiness may be evaluated by the MSLT, a series of five nap opportunities (sometimes four or six) with sleep recordings at 2-hour intervals throughout the day. "Normal" sleep for that individual is recommended for 7 days prior to the test, and any medications that can disrupt sleep architecture, particularly antidepressants, should ideally be discontinued 2 weeks prior to the study. Polysomnography should be performed the night prior to testing so that prior sleep is documented. If significant obstructive sleep apnea is noted on polysomnography, the MSLT is typically not performed. A minimum of 6 hours of sleep should occur during polysomnography to reliably proceed with an MSLT.

Sleep onset is defined as the first epoch of nonwakefulness. The nap is terminated 15 minutes after sleep onset. If no sleep occurs, each recording session is terminated after 20 minutes. The sleep latency (the time it takes to fall asleep) is determined for each nap and provides an objective measure of daytime sleepiness. If no REM sleep occurs in four naps, the test may be terminated. Similarly, if REM occurs in at least two of four naps, testing could be terminated early. If, however, REM has occurred in only one of four naps, the patient is generally given the fifth nap in order to determine whether narcolepsy is likely.

FIGURE 30.1 **A:** A 4-minute recording of stage R (rapid eye movement sleep) showing cessation of airflow with continued abdominal and chest movements during apneic pauses illustrated by the *red arrows*. Note the snoring ceases with airflow and oxygen saturation declines. This is consistent with obstructive sleep apnea. **B:** A 4-minute recording of N1 and N2 (nonrapid eye movement sleep) showing cessation of airflow and abdominal and chest movements illustrated by the *red arrows*. This is consistent with central sleep apnea. Abbreviations: ECG, echocardiography; EEG, electroencephalography; O_2, oxygen.

FIGURE 30.2 Single epoch of phasic R sleep (*red arrows* indicate rapid eye movements) with movements of both the left and right legs *(blue arrows)*. Abbreviations: ECG, echocardiography; EEG, electroencephalography; O_2, oxygen.

Sleep latency over the course of the naps is averaged (20 min is used as time onset if the patient does not fall asleep). Additionally, any REM periods are counted; REM within 15 minutes is considered abnormal. These are described as sleep-onset rapid eye movement periods (SOREMPs). If an SOREMP is obtained in the prior night polysomnography, this can also be taken into consideration.

The main indication of this study is to support the diagnosis of narcolepsy. Individuals with narcolepsy tend to have mean sleep latencies of 3 ± 3 minutes. However, 16% of normal individuals will have a sleep latency of less than 5 minutes. Patients with narcolepsy typically have a mean sleep latency of less than 8 minutes and demonstrate at least two naps with sleep-onset REM. Although there is significant overlap of the mean sleep latencies of normal individuals and those who complain of excessive sleepiness, normal is considered to be a mean sleep latency of greater than 10 minutes.

The SOREMPs can also be seen as a result of obstructive sleep apnea, sleep deprivation, drug(s) withdrawal, or narcolepsy; in these cases, only one is typically seen in an MSLT. Two SOREMPs have 78% sensitivity and 93% specificity for narcolepsy. Notably, no large systematically collected repository of normative MSLT data is known to exist, and normal values for individuals younger than 6 years of age have not been established. If the individual has an SOREMP during the overnight PSG, this also counts toward the total number obtained on the MSLT.

Maintenance of Wakefulness Test

The MWT measures the time a patient is able to remain awake in a low-light environment during four 40-minute (sometimes 20-min) attempts. The patient is instructed to remain awake in a semirecumbent position, without any stimulating behaviors. The test may provide more information about the patient's ability to sustain wakefulness, but the validity of test results to real-life experience is unclear. It is sometimes used to evaluate driving performance in individuals who may be at high risk for daytime sleepiness.

Sleep onset is defined as three epochs (90 s) of continuous stage 1 sleep or one epoch of any other stage of sleep. A total of 97.5% of normal sleepers stay awake for an average of 8 minutes or more during the MWT. Falling asleep in an average of less than 8 minutes during the test would be considered abnormal. Results show that from 40% to 59% of people with normal sleep stay awake for the entire 40 minutes of all four trials.

EVALUATION OF CIRCADIAN RHYTHM DISTURBANCES

As well as the intrinsic characteristic of a person's sleep, extrinsic factors placed on the timing of the sleep-wake cycle may disrupt the ability of an individual to sleep when necessary. Several variants have been described including the delayed and advanced sleep phase syndromes, shift work disorder, and jet lag disorder. Non–24-hour sleep syndrome, in which the internal clock is free running, is the most severe of these but is quite rare. Diagnosis may be made simply through history taking and documentation with a sleep diary; however, patient recall of sleep patterns over time may be limited. Actigraphy can be helpful to objectively document sleep patterns.

Actigraphy

The essence of actigraphy is based on the concept that movement is limited during sleep. A device typically worn on the nondominant wrist monitors movement over a specific duration of time, typically up to 2 weeks, and is typically correlated to a diary of activity (Fig. 30.3). The parameters on some devices can be used to assess specifics such as the frequency of limb movements that occur during sleep. Studies that compare actigraphy to sleep with polysomnography show that it is a reasonable, although not perfect, surrogate measurement for sleep. It is clearly not practical (or necessary) to do formal polysomnography for weeks at a time to determine sleep patterns.

Many commercially available applications now use the principle of actigraphy to allow patients to track their sleep. Actigraphy applications using smartphone accelerometers have limited use, as most require movement of the bed rather than the person, and are not well correlated with actual sleep. In contrast, other linked accelerometry devices may be worn on the body (typically the arm); these are likely reasonably similar to actigraphy and have potential to be viewed by the clinician to help with diagnosis and to monitor treatment progress.

Biomarkers of Circadian Rhythm

Several variables are used to evaluate the sleep-wake rhythm, principally for research purposes and to a lesser extent in clinical practice. Melatonin or its metabolites can be measured in the urine, blood, or saliva. Melatonin secretion begins in the evening hours and peak overnight. During the daytime hours, levels are barely detectable. Dim light melatonin onset (DLMO) is the point at which melatonin levels reach 2 pg/mL in plasma or 4 pg/mL in the saliva. It can also be measured as the mean of three daytime samples plus two standard deviations of these three daytime samples. It typically occurs 2 hours before bedtime provided that lighting is dim. The DLMO is considered the standard measure of circadian pattern. For example, a patient with delayed sleep phase phenomenon would have very late DLMO (3 to 5 AM). A patient with shift work sleep disorder would continue to show DLMO during the typical work shift.

Core body temperature usually peaks in the late afternoon. Sleep typically occurs on the downward slope and ends about 2 hours following the nadir. Loss of normal core body temperature rhythm can be diagnosed with continuous temperature monitoring, but this is not a convenient method for determining circadian pattern clinically.

SUBJECTIVE REPORTING OF SLEEP

In addition to reports of sleep complaints, a patient can keep a log of his or her sleep-wake cycle over time (Fig. 30.4). This can be used in combination with actigraphy, particularly when evaluating for paradoxical insomnia. It can also be used to visually evaluate potential sleep-wake disorders as well as help to ensure

FIGURE 30.3 Actogram of activity for 12 days. Each day is plotted on a row, and quantity of movement is indicated by *black*. This is typically correlated with a log by the individual. Periods with limited movement likely correlate with sleep *(red arrows)*. Periods of absolute lack of movement *(red stars)* suggest removal of the watch.

FIGURE 30.4 Sleep diary. The individual is asked to shade the boxes indicating the estimated sleep. Here, the individual has a delayed sleep phase syndrome typically not sleeping until 2 AM or later. Note that on the day of a nap in the afternoon, the individual remains awake during the typical hours of sleep. Further information could be added such as time of medication, times of caffeine intake or exercise, and time getting into and out of bed.

the patient is getting sufficient sleep prior to polysomnography, which may otherwise alter sleep architecture.

Many questionnaires related to sleep exist, with most particularly focusing on obstructive sleep apnea or snoring, whereas others may evaluate the quality of sleep, degree of sleepiness, or the inability to sleep. A frequently used questionnaire in many practices is the Epworth Sleepiness Scale. Rating eight situations on a scale of 0 to 3 for severity of sleepiness results in a possible total of 24. A level of 10 or more typically indicates excessive sleepiness. Persons with narcolepsy may have scores around 16, although this is varied between individuals. Not only is it used for diagnostic purposes but can also be quickly and easily used to monitor efficacy of treatment. It is important to know that the Epworth shows very limited correlation with the objective sleepiness seen on MSLT. Patients with severe sleepiness due to obstructive sleep apnea, for example, may be observed to fall asleep in the waiting room but score normally on the Epworth. This supports that patients are often unaware or in denial of their own sleepiness; nevertheless, the Epworth can be useful in documenting a patient's perception of his or her drowsiness.

Other questionnaires are typically used as a screening tool for potential sleep disorders. There are over 14 questionnaires that exist for the evaluation of sleep-disordered breathing. Although many can help increase the sensitivity for sleep apnea, the diagnosis can only be made through the use of polysomnography. There are also at least five available questionnaires to evaluate for REM sleep behavior disorder but ultimately, a PSG determines the diagnosis and excluded mimickers such as periodic limb movement disorder or obstructive sleep apnea.

INDICATIONS FOR LABORATORY TESTING

Narcolepsy

In rare circumstances or for research purposes, laboratory tests may be useful to confirm a suspicion of narcolepsy. In individuals who have narcolepsy type 1 (associated with cataplexy), a lumbar puncture can be performed. Cerebrospinal fluid levels of hypocretin-1 of less than 110 ng/mL are diagnostic with 87% sensitivity and 99% specificity for narcolepsy type 1. The majority of patients with idiopathic hypersomnia and narcolepsy type 2 have normal cerebrospinal fluid hypocretin-1 levels. Genetic testing can also be helpful in some circumstances. The allele HLA-DQB1*0602 is present in over 90% of individuals with narcolepsy type 1, 56% of type 2 narcolepsy, and 52% of individuals with idiopathic hypersomnia. However, it is found in between 12% and 35% of healthy individuals.

Restless Legs Syndrome

Restless legs syndrome (RLS) is a clinical diagnosis based on an urge to move limbs (not necessarily legs or a leg) that is typically worse in the evening or inactivity that is temporarily relieved by movement and not due to position, cramps, or pain (see Chapter 78). Secondary causes may include anemia, uremia, thyroid dysfunction, or venous disease. Of particular note is that a ferritin level of less than 50 μg/L, sometimes 75 μg/L despite being considered to be within the normal range, is treated with exogenous iron supplementation. A morning fasting ferritin is

recommended due to diurnal fluctuations. Single nucleotide polymorphisms in some genes have been associated with an increased risk of RLS; however, these are not diagnostic. For example, variants in the gene *BTBD9* can be seen in 75% of individuals with RLS but also in 65% of those who have never had the syndrome.

IMAGING

Imaging is not routinely performed as part of a workup for sleep disturbances. However, rare presentations of narcolepsy have resulted from strokes or demyelinating lesions in the brainstem. Hypoperfusion in the thalami of individuals with Kleine-Levin syndrome during symptomatic periods can be seen on single-photon emission computed tomography or positron emission tomography imaging. Brain imaging should be considered in any individual with respiratory arrests not typical of obstructive sleep apnea or that occur during wakefulness. In a subset of individuals with congenital central hypoventilation syndrome—respiratory arrests during sleep, typically seen in childhood as a result of inborn failure of autonomic control of breathing—there is a higher incidence of neural crest tumors such as neuroblastomas.

Neuropsychological Evaluation 31

Yaakov Stern

KEY POINTS

1. Neuropsychological evaluation is important for differential diagnosis as well as for characterizing the cognitive status.
2. Most tests are designed to evaluate specific cognitive functions.
3. Mental status tests can be used for quicker screening.
4. Careful characterization of the referral question will help yield more useful information.

Neuropsychological testing can assist in the diagnosis of dementia, in evaluating or quantifying cognition and behavior in development, brain diseases, and clinical treatment. It is also incorporated into research that evaluates cognitive functions in healthy and diseased individuals.

STRATEGY OF NEUROPSYCHOLOGICAL TESTING

Conditions that affect the brain often cause cognitive, motor, or behavioral impairment that can be detected by appropriately designed tests. Defective performance on a test and certain patterns of test performance may suggest specific pathology. Alternatively, patients with known brain changes may be assessed to determine how the damaged brain areas affect specific cognitive functions. Before relating test performance to brain dysfunction, however, other factors that affect test performance must be considered.

Typically, test performance is compared with normative values derived from populations similar to the patient in age, education, socioeconomic background, and other variables. Scores significantly below the mean expected values imply impaired performance. Performance sometimes can be evaluated by assumptions about what might be expected from the average person (eg, repeating simple sentences or simple learning and remembering).

Unfortunately, comparable data may not exist for the patient being tested. This problem is common in the elderly and those with language and cultural differences. This situation may be addressed by collecting local, normal characteristics that are more descriptive of the local clinical population or by evaluating the cognitive areas that remain intact. In this way, the patient guides the clinician in terms of the level of performance that should be expected in possibly affected domains. Other factors that also influence test performance include the patient's current mood, anxiety, depression or other psychiatric disorders, medication, and the patient's motivation to participate fully.

Patterns of performance, such as strengths in some cognitive domains and weaknesses in others, have been associated with specific conditions, based on empiric observation and knowledge of the brain pathology associated with those conditions. Observation of these patterns may aid in diagnosis.

TEST SELECTION

Neuropsychological tests in an assessment battery come from many sources. Some were developed for academic purposes (eg, intelligence tests), and others for experimental psychology. The typical clinical battery consists of a series of standard tests that have been proved useful and are selected for the referral issue. These tests should have established reliability and validity. A trade-off exists between the breadth of application and ease of interpretation, available from standard batteries, and the ability to pinpoint specific or subtle deficits, offered by more experimental tasks that are useful in research but have not yet been standardized.

Most tests are intended to measure performance in specific cognitive or motor domains, such as memory, spatial ability, language function, or motor agility. These domains may be subdivided (eg, memory may be considered verbal or nonverbal; immediate, short term, long term, or remote; semantic or episodic; public or autobiographic; or implicit or explicit). However, no matter how focused a test is, multiple cognitive processes are likely to be invoked. An ostensibly simple task, such as the Wechsler Adult Intelligence Scale (WAIS) Coding subtest (previously called *Digit Symbol Coding*), which uses a table of nine digit-symbol pairs to fill in the proper symbols for a series of numbers, assesses learning and memory, visuospatial abilities, motor abilities, attention, and speeded performance. In addition, tests may be failed for more than one reason: Patients may draw poorly because they may not appreciate spatial relationships, because they plan the construction process poorly, or because they are distractible or lack motivation. Thus, relying solely on test scores may lead to spurious conclusions.

TESTS USED IN A NEUROPSYCHOLOGICAL EVALUATION

Intellectual Ability

Typically, a test such as the fourth edition of WAIS (WAIS-IV) or the fourth edition of the Wechsler Intelligence Scale for Children is used to assess the present level of intellectual function for adults and children, respectively. These tests yield a global IQ score and index scores that are standardized, so that 100 is the mean expected value at any age (with a standard deviation of 15).

The WAIS-IV consists of 10 core and 5 supplemental subtests (Table 31.1). The 10 core subtests comprise the full-scale IQ. In previous WAIS versions, verbal and performance IQ estimates were calculated. In contrast, the WAIS-IV emphasizes a

TABLE 31.1 Subtests of the Wechsler Adult Intelligence Scale Fourth Edition Arranged by the Four Index Groups[a]

Verbal Comprehension	**Verbal Concept Formation, Verbal Reasoning, Knowledge Acquired From Environment**
Similarities	Derive relevant superordinate category or similarity for word pairs; abstract verbal reasoning
Vocabulary	Name pictures and define words; often used to assess "premorbid" level of ability
Information	Answer questions that address a broad range of general knowledge topics; ability to acquire, retain, and retrieve general factual knowledge
(Comprehension)	Answer questions based on understanding of general principles and social situations
Perceptual Reasoning	**Perceptual and Fluid Reasoning, Spatial Processing, Visual Motor Integration**
Block Design	Arrange blocks with red, white, and half-red and half-white sides to form 14 designs; spatial perception, visual abstract processing, and problem solving
Matrix Reasoning	Identify the picture that completes a pattern using pattern completion, classification, analogy, or serial reasoning; classic measure of fluid intelligence
Visual Puzzles	View a completed puzzle and select three response options that, when combined, reconstruct the puzzle; visual perception and organization, nonverbal reasoning
(Picture Completion)	Determine the missing feature in pictures; visual perception
(Figure Weights)	View a scale with missing weight(s) and select the response option that keeps the scale balanced; quantitative and analogical reasoning
Working Memory	**Attention, Concentration, Mental Control, Reasoning**
Digit Span	Standardized assessment of digits forward and backward. In addition, hear a sequence of numbers and recall the numbers in ascending order; attention, concentration, mental control
Arithmetic	Verbal arithmetic problems; mental manipulation, concentration, attention, short- and long-term memory, numerical reasoning ability
(Letter-Number Sequencing)	Listen to a combination of numbers and letters and recall first the numbers in ascending order and then the letters in alphabetical order; sequential processing, mental manipulation, attention, concentration, memory span, short-term auditory memory
Processing Speed	**Ability to Quickly and Correctly Scan, Sequence, and Discriminate Simple Visual Information, Short-Term Visual Memory, Attention, Visual-Motor Coordination**
Symbol Search	Scan a search group and indicate whether one of the symbols in the target group matches; processing speed, visual discrimination
Coding	Using a key, copy symbols that are paired with numbers; processing speed, short-term visual memory
(Cancellation)	Scan a structured arrangement of shapes and mark target shapes; processing speed, visual selective attention

[a]Supplementary subtests are indicated by parentheses. Comments describe the subtests and identify some select cognitive features that they tap.

set of index scores, based on groups of subtests, each assessing a broad, separate class of cognitive abilities. These include Verbal Comprehension, Perceptual Reasoning, Working Memory, and Processing Speed. The WAIS-IV also adds a General Ability Index, which consists of selected subtests from the Verbal Comprehension and the Perceptual Reasoning subtests. The intention of this index score is to assess cognitive abilities that are not as susceptible to changes in processing speed and working memory. For the individual subtests, scaled scores range from 1 to 19, with a mean of 10 and a standard deviation of 3; the average range for subtest scaled scores is from 7 to 13.

The overall IQ and index scores supply summary information about the level of general intelligence and broad ability categories. The neuropsychologist is often more interested in the "scatter" of subtest scores, which indicates strengths and weaknesses. The subtests are often better considered as separate tests, each assessing specific areas of cognitive function. There are many other tests of general intelligence, including some that are nonverbal.

Global cognitive function can also be evaluated at the bedside using a simple abbreviated cognitive screening test such as the Mini-Mental State Examination of the Montreal Cognitive Assessment (Fig. 31.1). These tests take approximately 15 minutes to perform, and yield a total score below which dementia should be considered.

Memory

The subclassifications of memory have evolved from clinical observation and experimentation; most are important to the assessment (Table 31.2).

For example, preservation of remote memories, despite the inability to store and recall new information, is the hallmark of specific amnestic disorders. Other subclassifications are used to evaluate different clinical syndromes.

Processing Speed

Processing speed is defined as either the amount of time it takes to process a set amount of information or the amount of information that can be processed within a certain amount of time. In the WAIS-IV, it is assessed with the Coding and Symbol Search subtests. Another commonly used test is pattern comparison, where two patterns are presented and the test taker must decide as quickly as possible if they are the same or different.

Perception

Neuropsychologists may provide a standardized version of neurologists' perceptual tasks: double (simultaneous) stimulation

FIGURE 31.1 The Montreal Cognitive Assessment (MoCA).

TABLE 31.2 Typical Subclassifications of Memory Addressed by Neuropsychologic

Verbal and nonverbal	Memory for material that is or is not verbally encoded
Immediate, short term	Length of time between exposure to material and recall. The length of time has implications for how long term and remote the memory may be stored and retrieved.
Semantic and episodic	Memory for encodable knowledge, such as vocabulary or facts about the world, as opposed to memory for events
Public and autobiographic	Memory for public, commonly known events vs events that occurred in one's own life
Implicit and explicit	Memory tested on tasks that do not require conscious, explicit recollection of recent exposures (such as motor skills, procedural skills, classical conditioning, or priming) vs tasks that demand explicit recall of prior information (such as recall or recognition tasks)
Working	Similar to what in the past has been called short-term memory, working memory provides a buffer for briefly holding on to information, such as a telephone number or the name of a newly met person. It is also important for tasks that require mental manipulation of information, such as multistep arithmetic problems. For many theorists, working memory also has a more important role at the work space where recalled information is actually used, manipulated, and related to other information, allowing complex cognitive processes such as comprehension, learning, and reasoning to take place.

in touch, hearing, or sight; stereognosis; graphesthesia; spatial perception; or auditory discrimination.

Some tasks tap basic perceptual abilities. For example, the Benton Judgment of Line Orientation test assesses a person's ability to match the angle and orientation of lines.

Construction

Construction, typically assessed by drawing or assembly tasks, requires both accurate spatial perception and an organized motor response. The Block Design subtest of the WAIS-IV is examples of assembly tasks. In the Rey-Osterrieth Complex Figure, the patient is asked to copy a figure that contains many details embedded within an organizing framework. In addition to the scores these tests yield, the clinician attends to the patient's construction performance to determine factors that may underlie poor performance (eg, a disorganized impulsive strategy may be more related to anterior brain lesions, whereas difficulty aligning angles may arise from parietal lobe injury).

Language

"Mapping" of different aphasic disorders to specific brain structures was one of the early accomplishments of behavioral neurology. In neuropsychological assessment, this model is often followed. Individual tests of comprehension, fluency, repetition, and naming are used to assess spoken or written language. Fluency refers to the ability to use one or more strategies that maximize the production of responses while avoiding response repetition. Two types of verbal fluency tasks are phonemic: letter fluency, where the patient is given a fixed period of time to name as many words as possible that begin with a specific letter, and semantic, where the task is to name as many words as possible in a specific category.

More extensive batteries are available, such as the Boston Diagnostic Aphasia battery. Language deficits typically indicate dominant hemisphere pathology, although specific patterns of language difficulties are also evident in various forms of dementia, including the primary progressive aphasias.

Executive Function

The ability to plan, sequence, monitor, and inhibit behavior has been called *executive function*. These functions, often linked to the prefrontal cortex, rely on and organize other intact cognitive functions that are required components for performance. Several schemes for classifying executive functions: For example, Miyake et al (2000) identified three separable functions in a meta-analytic study: mental set shifting, information updating and monitoring, and inhibition of prepotent responses. Here, I summarize several task classifications typically included under the umbrella of executive function. Others, not described here, include planning, insight, and social cognition and behavior.

Working Memory

Working memory describes the ability to hold several pieces of information in the mind for a short period of time and manipulate them. For example, the Letter-Number Sequencing subtest of the WAIS-IV requires patients to listen to a series of randomly ordered letters and numbers and then state first the numbers in numerical order and letters in alphabetical order.

Inhibition

One test of inhibition is the Stroop Color-Word Test. The patient is given a series of color names printed in contrasting ink colors (eg, the word *blue* printed in red ink) and is asked to name the color of the ink. The response set must be maintained while the subject suppresses the alternate (and more standard) inclination to read words without regard to the color of the print.

Set Shifting

Set shifting tasks require the testee to shift attention between one task and another or to alternate strategies. One commonly used task is the Wisconsin Card Sorting Test, which uses symbols that may be sorted by color, number, or shape. Based only on feedback about whether each card was or was not correctly placed, the subject must infer an initial sort rule. At intervals, the sort rule is changed without the subject's knowledge; subjects must switch based only on their own observation that the current rule is no longer effective. Other set shifting tasks use explicit use a fixed set of rules that do not change, such as the Trail Making Test.

Motor and Praxis

Tests of motor strength, such as grip strength, and of motor speed and agility, such as assessing speed and peg placement, establish lateral dominance and focal point of impairment. In some diseases, such as the dementia of AIDS, reduced motor agility is

part of the diagnosis. Tasks such as the grooved pegboard assess manual dexterity and sensorimotor integration. They can identify lateralized brain damage since both hands are tested. The grooved pegboard task contains 25 holes with randomly positioned slots and pegs, which have a key along one side. Pegs must be rotated to match the hole before they can be inserted. The patient is asked to insert the pegs into the holes as rapidly as possible.

Higher order motor tasks, such as double alternating movements or triple sequences, are used to assess motor sequencing or programming, as opposed to pure strength or speed.

Attention

The ability to sustain attention is often tested by cancellation tasks, in which the patient must detect and mark targets embedded in distractors, or by computerized continuous performance tests, which measure accuracy, response time, and variability in response time as a function of time on task. Continuous performance tests assess sustained attention over relatively long time intervals (10-20 min) and are frequently used in the assessment of attention deficit disorder. Mental tracking tasks such as Digit Span Forward may also be included in this category.

Concept Formation and Reasoning

Brain damage is often associated with concrete reasoning. Tests of concept formation include verbal tasks, such as proverb interpretation, and nonverbal tasks, where underlying concepts must be extracted from visual displays. Tests of abstract reasoning include the Similarities subtest of the WAIS-IV, where the subject must explain how two words are alike. The quality of the response is judged. A general classification response that is pertinent to both words receives a higher score than a specific property or function that is relevant to both.

Perceptual reasoning can be assessed with tasks such as matrix reasoning. This task usually involves a series of figures in which there is a discernible pattern, with one figure in the series left blank. The patient is asked to choose, from an array of possibilities, what figure would complete the series or pattern.

Personality and Emotional Status

Mood may affect test performance. At minimum, the neuropsychologist notes the psychiatric history and probes for current psychiatric symptoms. Standardized mood rating scales are also available. Many neurophysiologists use standardized personality scales to aid in diagnosis and test interpretation.

CLINICAL OBSERVATION

Along with the formal scores, the intake interview and testing period afford an extensive period to observe the patient under controlled conditions. These clinical observations are valuable for diagnosis. Formal test scores capture only certain aspects of performance. The patient's problem-solving approach or the nature of the errors made may be telling. Also important in timed tasks is determining whether the patient may complete them with additional time or is actually incapable of solving them. Another important dimension of assessment is the patient's ability to learn and follow directions for the many tests.

More subtle aspects of behavior include responses or coping abilities when confronted with difficult tasks, the ability to remain socially appropriate as the session progresses, and the subjects' appreciation of their own capacities.

MENTAL STATUS TESTING

Several brief mental status tests have been developed for rapid screening for cognitive impairment. These are often used in the clinician's office, or in studies tracking progression of cognitive change. One of the most ubiquitous is the Mini-Mental State Evaluation (MMSE). This is a 30-point questionnaire that examines orientation; registration of three items for recall, attention, and calculation (serial sevens, or spell WORLD backward); delayed recall; language (repetition, naming, writing a sentence, following simple oral and written commands); and construction (intersecting pentagons).

The Montreal Cognitive Assessment was introduced in 2005. It is also a brief, 30-question test but contains some more diverse items than the MMSE, including tests of executive function, abstraction, and verbal fluency. The immediate and delayed recall task contains five items, compared to the three on the MMSE, and the learning phase of the memory task is standardized into two trials.

The Montreal Cognitive Assessment may be more sensitive than the MMSE to cognitive changes in non–Alzheimer disease dementias because of its inclusion of the additional cognitive domains.

DIAGNOSIS-SPECIFIC ISSUES

Neuropsychological testing is useful for the diagnosis of some conditions and is a tool for evaluating or quantifying the effects of disease on cognition and behavior. The tests may assess the beneficial or adverse effects of drug therapy, radiation, or surgery. Serial evaluations give quantitative results that may change with time. In temporal lobectomy for intractable epilepsy, tests that help identify the location of dysfunction are required in presurgical evaluation to minimize the possibility of adverse effects. Specific referral issues are summarized in the following paragraphs.

Dementia

Testing may detect early dementing changes and discriminate them from "normal" performance. It also helps to obtain information contributing to differential diagnosis, either between dementia and nondementing illness, such as depression versus dementia, or between alternate forms of dementia (eg, Alzheimer disease, dementia with Lewy bodies, or vascular dementia). Test results may also confirm or quantify disease progression and measure efficacy of clinical interventions.

Other Brain Disease

The effects on cognitive function of stroke, cancer, head trauma, Parkinson disease, Huntington disease, multiple sclerosis, brain infection, or other conditions may be investigated. Testing may be prompted by the patient's complaints. The evaluation helps to clarify the cause or extent of the condition.

Epilepsy

Testing is part of the presurgical evaluation to determine whether cognitive deficits are consistent with EEG and possibly magnetic resonance imaging evidence of focal dysfunction. Additionally, test results, together with knowledge of the proposed surgery, can be used to predict risk of postoperative cognitive decline or the probability of postoperative improvement. Nonsurgical patients are frequently assessed to address memory, attention, and mood issues associated with epilepsy and antiepileptic medications.

Deep Brain Stimulation

Neuropsychological evaluation prior to deep brain stimulation can identify existing impairments in cognitive function. Lower cognitive function in general can be predictive of poorer cognitive outcome. Also, based on implant location, specific deficits may be associated with greater risk of a poor cognitive outcome. Postsurgical evaluation is important for detecting potential adverse effects.

Toxic Exposure

Testing may evaluate the consequences of toxic or potentially toxic exposures, either on an individual basis or for particular exposed groups (eg, factory workers). Exposures may include metals, solvents, pesticides, alcohol and drugs, or any other compounds that may affect the brain.

Medication

The potential effect of medications on the central nervous system may be evaluated in therapeutic trials or clinical practice. For example, in trials of agents used to treat Alzheimer disease, neuropsychological tests are typically primary measures of drug efficacy. In clinical practice, adverse or therapeutic effects of newly introduced medications may be evaluated.

Psychiatric Disorders

Testing may help in the differential diagnosis of psychiatric and neurologic disorders, especially affective disorders and schizophrenia. It may also assess cognition and areas of competence in patients with these conditions. For example, individuals with schizophrenia can have impairments in attention, executive functions, episodic memory, certain aspects of working memory performance, and processing speed, with relatively spared language functions, perceptual processes, and nondeclarative memory.

Learning Disability

Testing may evaluate learning disabilities and the residuals of these disabilities in later life. Behavioral disorders, attention deficit disorder, autism, dyslexia, and learning problems are common referral issues. The evaluation can evaluate the specific functions that are often involved in learning disabilities, such as auditory-linguistic abilities, visual abilities, memory, processing speed, cognitive efficiency, and reasoning. In addition, it can assess functions that might enhance or detract from overall performance, such as attention or motor and sensory abilities.

EXPECTATIONS FROM A NEUROPSYCHOLOGICAL EVALUATION

The minimum that a neuropsychological evaluation yields is an extensive investigation of the abilities of the patient. In these cases, although the studies do not lead to a definite diagnosis, they help determine the patient's capacities, establish a baseline from which to track the future, and advise the patient and family.

Sometimes, the evaluation suggests that additional diagnostic tests would be useful. For example, if a patient's pattern of performance deviates substantially from that typically expected at the current stage of dementia, a vascular contribution may be considered. Similarly, evaluation may suggest the value of psychiatric consultation or more intensive electroencephalographic recordings.

Many times, the neuropsychologist may offer a tentative diagnosis or discuss the possible diagnoses compatible with the test findings. Neuropsychological evaluation may not yield a diagnosis without appropriate clinical and historical information. In the context of multidisciplinary testing, however, it may provide evidence to confirm or refute a specific diagnosis. In this case, testing might best be considered an additional source of information to be used by the clinician for diagnosis in conjunction with the neurologic examination and laboratory tests.

HOW TO REFER

The more information the examiner has at the start, the more directly the issues may be addressed. For example, if the magnetic resonance imaging has revealed a particular lesion, tests may be tailored specifically to better understand the lesion. The examination is not an exploration of the ability to detect a lesion but is rather a contribution to understanding the implications of the lesion. Similarly, the more explicit the referral question, the more likely the evaluation may yield useful information. Besides providing the relevant history, a useful referral describes the problem to be assessed. This is often a statement of the differential diagnosis being entertained. Alternately, the neurologist or the family may simply want to document the current condition or explore some specific aspect of performance, such as language.

32 Lumbar Puncture and Cerebrospinal Fluid Analysis

Kiwon Lee

KEY POINTS

1. Lumbar puncture is essential in assessing patients with potential central nervous system infection, and it is important to remember typical cerebrospinal fluid profiles in common diseases.
2. One needs to understand the limitations of the cerebrospinal fluid analysis caused by confounders such as traumatic tap and concurrent acute inflammatory processes such as aneurysmal subarachnoid hemorrhage (eg, red blood cell:white blood cell ratios).

INTRODUCTION

Accessing the cerebrospinal fluid (CSF) compartment—typically via lumbar puncture (LP)—is one of the key skills every neurologist should have. Proper analysis of CSF findings may result in a diagnosis (even if the neurologic examination and neuroimaging have not); furthermore, LP and the removal of CSF may be therapeutic in certain cases. This chapter reviews step by step the technique of the LP, including advances in the procedure (eg, ultrasound guidance); in addition, we outline here a guide for the interpretation of CSF findings in various neurologic disorders ranging from infectious to demyelinating to neoplastic. A new section on precaution for patients with hemicraniectomy has been added for this edition.

LUMBAR PUNCTURE

Techniques

Careful positioning of the patient is often the key to performing a successful LP. Patients may be placed in either a lateral recumbent position with the spine flexed—head bowed, knees bent, and drawn up into the torso, for example, the "fetal position" (Fig. 32.1). Alternatively, patients may sit upright with the neck and back flexed forward (typically resting on a table). The lateral recumbent position should be used if an opening pressure is needed. As the conus medullaris ends at the level of the L1 and L2 interspace in 94% of adults, this level should be avoided during LP. Instead, the L3-L4, L4-L5, and L5-S1 interspaces are appropriate for needle puncture. These interspaces can be identified via palpation of bony landmarks. The line joining the superior aspect of the iliac crests posteriorly (the intercristal line) identifies the L4 spinous process or L3 and L4 interspace.

The interspace for needle insertion should be marked, and the skin overlying the LP site should be sterilized and draped using standard aseptic technique. Local anesthetic—usually 1% lidocaine—is then applied; the 25-gauge needle should be used to raise a skin wheal at the LP site and the longer, 20-gauge needle should then be used to infiltrate the deeper layers. The spinal needle (with stylet in) is then inserted through the skin wheal into the interspinous space. Ideally, needle insertion should be midline, orthogonal to the plane of the back. To reduce the risk of post-LP headache, the bevel should be parallel to the longitudinal fibers of the dura; if the patient is in the lateral recumbent position, the bevel should face up, and if the patient is sitting upright, the bevel should face to one side. Theoretically, this allows dural fibers to be separated rather than cut. The spinal needle is then advanced slowly at a slightly cephalad angle (directed toward the umbilicus) in order to follow the contour of the spinous processes. The needle passes through the supraspinous ligament and the ligamentum flavum, perhaps resulting in a "pop" when the dura is pierced and the subarachnoid space is entered. The stylet should then be removed, and CSF should readily appear at the needle hub if in the subarachnoid space. If instead CSF does not flow, the stylet should be replaced and the needle advanced or withdrawn incrementally, with frequent removal of the stylet, until CSF is obtained or bone encountered.

Ultrasound Guidance

Ultrasound visualization of landmarks may significantly improve the rate of LP success. This is particularly true in certain patient populations where palpation of landmarks may be challenging—neonates, pregnant women, obese patients, and patients with generalized edema, for example. One large meta-analysis of 14 studies and 1,334 patients revealed a significant reduction in the risk of failed or traumatic LPs and epidural catheterizations with the use of ultrasound guidance.

FIGURE 32.1 Proper positioning for lumbar puncture. Position the patient's back at the edge of the bed with the head flexed and the legs curled up in the fetal position. Place a pillow under the head. Hips are parallel to each other and perpendicular to the bed. The spinal needle should be parallel to the bed. (Adapted from Marshall R, Mayer S. *On Call Neurology*. 3rd ed. Philadelphia, PA: Saunders; 2007.)

FIGURE 32.2 Ultrasound-guided lumbar puncture. **A:** Transverse view. The anechoic shadow below *A* represents the spinous process—the midline; *B* localizes the transverse process. **B:** Longitudinal view. The interspace *(asterisk)* is located between the two crescentic-shaped, hyperechoic spinous processes (*S*).

To perform an ultrasound-guided LP, the linear probe (higher resolution of superficial structures) should be used. The first view that should be obtained is the transverse view—the goal of this view is to determine an accurate anatomic midline by identification of the spinous process (Fig. 32.2A). To obtain this view, the probe is placed perpendicularly to the long axis of the spine. The spinous process will appear as a hyperechoic white convex rim with an anechoic shadow (or the anechoic shadow itself can simply be used if the rim is not identified). The midline should be marked and the longitudinal view should then be obtained (using the midline as a reference). The goal of the longitudinal view is to determine the spinal interspace—where the spinal needle will be inserted. To obtain this view, the transducer should be rotated into the sagittal/longitudinal plane with the probe marker pointing cephalad. Identify the hyperechoic spinous process again and then adjust the probe cephalad and caudal in order to center the probe/image between two contiguous, crescentic-shaped spinous processes; the interspace will be the hypoechoic gray gap in between (Fig. 32.2B). This interspace should also be marked. Remove the probe and extend the transverse/longitudinal markings until they intersect; this intersection represents the ideal position for the spinal needle to be inserted.

CEREBROSPINAL FLUID ANALYSIS

Cerebrospinal Fluid Pleocytosis

Basic analysis of the CSF begins with red blood cell (RBC) and white blood cell (WBC).analysis and measurements of protein and glucose, although an extensive variety of additional tests can also be ordered (Table 32.1). The normal WBC count of CSF ranges from 0 to 5 lymphocytes or monocytes per cubic millimeter. Rarely, a single polymorphonuclear (PMN) cell may be identified from a large volume tap; the presence of two or greater PMNs, although, should be considered abnormal. A myriad of neurologic

TABLE 32.1 Cerebrospinal Fluid Tests

Common tests
• Cell counts and differentials
• Protein and glucose levels
• Gram stain and culture
Less common tests
• VDRL test
• India ink test (for *Cryptococcus neoformans*)
• Wet smear (for fungi and amebae)
• Stain and culture for AFB (for tuberculosis)
• Cryptococcal antigen titers
• pH and lactate levels (abnormal in MELAS)
• Oligoclonal bands (abnormal in multiple sclerosis)
• IgG index (intrathecal IgG production)
• IgG and IgM antibody titers (for viral infections, compare to serum)
• Lyme disease antibody titers (compare with serum titers) and Western blot
• Latex agglutination bacterial antigen tests (for pneumococcus, meningococcus, and *Haemophilus influenzae*)
• Viral isolation studies
• Cytology (requires fixation in formalin)
• Polymerase chain reaction for Lyme disease, tuberculosis, and causes of viral encephalitis including SARS-CoV-2
• CSF ACE activity (abnormal with tuberculosis or sarcoidosis)
• 13-9-9 protein and RT-QuIC (elevated in Creutzfeldt-Jacob disease)

Abbreviations: ACE, angiotensin-converting enzyme; AFB, acid-fast bacilli; CSF, cerebrospinal fluid; IgG, immunoglobulin G; IgM, immunoglobulin M; MELAS, mitochondrial encephalomyopathy, lactic acidosis, and stroke; RT-QuIC, real-time quaking-induced conversion; SARS-CoV-2, severe acute respiratory syndrome due to novel coronavirus; VDRL, Venereal Disease Research Laboratory.

disorders can result in a CSF pleocytosis, ranging from acutely life-threatening (bacterial meningitis) to entirely chronic (as can be seen in patients with HIV). A common neurologic disorder such as seizure may cause mild pleocytosis (0-12 white blood cells).

Assessing the magnitude of pleocytosis along with the relative predominance of neutrophils to lymphocytes is often key, as is the clinical history—specifically whether the neurologic symptoms are acute or chronic in nature. For instance, a patient presenting with acute encephalopathy and a neutrophil-predominant CSF pleocytosis should be presumed to have bacterial meningitis (and promptly treated as such). In general, patients with acute bacterial meningitis have a CSF WBC count of several thousand (although the range may be from hundreds to >60,000). Furthermore, a CSF sample with greater than 33% neutrophils, a protein concentration of greater than 100 mg/dL, and a glucose level of less than 50% of the serum glucose level is strongly suggestive of bacterial meningitis. Exceptions include bacterial meningitis due to *Listeria* (often with a lymphocytic rather than neutrophilic pleocytosis), early viral or atypical (fungal/mycobacterial) infections that may initially recruit neutrophils into the CSF, neuroinvasive disease due to West Nile virus, and neuroinflammatory disorders (neuro-Behçet, Sweet syndrome).

In an acutely ill patient with a lymphocytic CSF pleocytosis, viral meningoencephalitis is often the cause. The WBC count generally ranges from 10 to 1,000 cells/mm^3 and is composed primarily of mononuclear cells. The cornerstone of etiologic diagnosis is the detection of viral nucleic acid sequences in the CSF via polymerase chain reaction (PCR). In cases of suspected viral meningoencephalitis, CSF PCRs for the enteroviruses along with the herpesviruses (herpes simplex virus 1 and 2, cytomegalovirus, varicella-zoster virus, Epstein-Barr virus [EBV], and in immunocompromised patients, human herpesvirus-6) should be sent, along with serologic testing for HIV. Serologic testing for several additional viruses can be considered (West Nile virus, St. Louis encephalitis virus, Eastern equine encephalitis virus, Venezuelan equine encephalitis virus, and La Crosse virus).

In patients with chronic neurologic symptoms and a lymphocytic CSF pleocytosis, an atypical infection such as fungal, tuberculous, or spirochetal should be considered. Etiologic diagnosis can be made via these CSF studies: India ink staining, fungal cultures, assays for cryptococcal antigen or histoplasma antigen, and *Coccidioides* complement fixation antibodies; acid-fast bacilli smear and culture, PCR for *Mycobacterium tuberculosis*; Venereal Disease Research Laboratory in conjunction with serum testing for syphilis; and antibodies against *Borrelia burgdorferi*. A chronic lymphocytic CSF pleocytosis may also be caused by various noninfectious disorders, including neoplasm (central nervous system [CNS] lymphoma, leptomeningeal carcinomatosis), paraneoplastic encephalitides, autoimmune/demyelinating disorders (CNS vasculitis, neurosarcoidosis, neuromyelitis optica [NMO], multiple sclerosis [MS]), and even medications or toxins (nonsteroidal anti-inflammatory drugs, sulfa drugs, intravenous immunoglobulin [Ig], carbamazepine). The clinical history along with neuroimaging is often vital for the diagnostic interpretation of a chronic lymphocytic CSF pleocytosis. Clinicians should also remember that there are three scenarios by which chronic hydrocephalus may occur: fungal, tuberculous, and partially treated other bacterial meningitis.

In December 2019, severe acute respiratory syndrome due to novel strain of corona virus has spread to numerous countries worldwide, leading to a pandemic. Reports have been variable with respect to the CSF profiles of infected hosts. For patients with positive nasal or saliva test for severe acute respiratory syndrome due to novel strain of coronavirus, the CSF analysis may or may not show any virus on real-time PCR test, making it difficult to assess or confirm CNS involvement. Due to its natural tendency for prothrombotic state, patients may suffer from pure meningoencephalitis or both arterial or venous thrombotic complications.

The CSF findings in the various meningitides are summarized here in Table 32.2.

There are two frequently encountered caveats to the interpretation of a CSF pleocytosis—the first being CSF obtained from a traumatic LP and the second being CSF obtained from an external ventricular drain (EVD). Inadvertent needle trauma to a capillary or venule during LP will introduce additional WBCs from the peripheral blood into the CSF, increasing the total number of WBCs. A useful rule of thumb if a traumatic LP is suspected is to subtract 1 WBC for every 500 to 1,000 RBCs present in the CSF. In other words, a WBC to RBC ratio of 1:500 to 1,000 is compatible with traumatic tap rather than infectious etiology.

TABLE 32.2 Cerebrospinal Fluid Findings in Various Meningitides

Type	Leukocytes (mm^3)	Protein (mg/dL)	Glucose (mg/dL)
Acute bacterial	>1,000 although ranges from several hundred to >60,000; PMNs predominate.	100-500, occasionally >1,000	5-40; typically a CSF-to-serum glucose ratio of <0.33
Viral	5-1,000; lymphocytes predominate (although early in the disease course, PMNs may predominate).	Frequently normal or slightly elevated; generally <100	Normal (although rarely reduced in cases of LCMV, CMV, paramyxoviruses, HSV)
Tuberculous	25-100; rarely >500; lymphocytes predominate (although early in the disease course, PMNs may predominate).	Elevated; 100-200	Low; <45 in 75% of cases
Cryptococcal	0-800; lymphocytes predominate.	20-500	Often reduced; average 30
Syphilitic	Average 500; primarily lymphocytes	100	Generally normal although may be mildly reduced
Sarcoid	0 to <100	Slight to moderate elevation	May be reduced in 18%-50% of patients
Leptomeningeal carcinomatosis	0 to several hundred; cytology may reveal malignant cells.	Elevated	Low in 40%-75% of cases

Abbreviations: CMV, cytomegalovirus; CSF, cerebrospinal fluid; HSV, herpes simplex virus; LCMV, lymphocytic choriomeningitis virus; PMNs, polymorphonuclear cells.

Alternatively, the following formula can be used, especially in patients with an abnormal peripheral WBC count:

$$WBC\ (CSF) = \frac{WBC\ (blood) \times RBC\ (CSF)}{RBC\ (blood)}$$

In the neurocritical care unit, patients may have an EVD inserted into the lateral ventricle to aid in CSF diversion or to monitor intracranial pressure. CSF can be easily sampled through this drain and is often sampled to exclude nosocomial meningitis/ventriculitis associated with the drain itself. Whether a truly pathologic pleocytosis (eg, one due to meningitis/ventriculitis) is present in EVD-sampled CSF can be challenging to ascertain; patients who have EVDs inserted for CSF diversion may have high RBC counts in the ventricular system (eg, those with subarachnoid hemorrhage or intracerebral hemorrhage) and the aforementioned corrections for RBCs are not entirely valid for EVD CSF samples. Furthermore, patients with large volumes of blood in the subarachnoid or ventricular compartments often develop an inflammatory response with an elevation in the WBC count in ventricular CSF. To aid with the diagnosis of meningitis/ventriculitis in patients with EVDs, the cell index, in conjunction with CSF Gram stain and culture, can be used. The cell index is calculated as follows:

$$Cell\ index = \frac{WBC\ (CSF) \div RBC\ (CSF)}{WBC\ (blood) \div RBC\ (blood)}$$

A cell index of 1 is (by definition) normal. And although there is no explicit cutoff for an "abnormal" cell index, a significant rise in the cell index from 1 day to the next may signal the presence of infection. It is important to understand that CSF pleocytosis alone is not sufficient to make the diagnosis of EVD infection or ventriculitis because blood products have been introduced to the subarachnoid and ventricular space. The concept of so called, "chemical meningitis" refers to inflammatory CSF pleocytosis rather than true infectious process. In order to avoid false-positive EVD infection claims, it is prudent to collect daily CSF profiles and track the *trend*, rather than one-time absolute value, of WBC to RBC ratio as well as other parameters such as CSF glucose levels and culture data.

Hypoglycorrhachia

A reduced CSF glucose level may be caused by impaired glucose transport into the CSF (eg, due to severe disruption of the blood-brain barrier and its glucose transporter, GLUT1) or as a result of increased glucose use within the CNS. There are a handful of pathologies that typically result in an abnormally low CSF glucose and as such, hypoglycorrhachia can be a very helpful diagnostic clue. In general, a CSF glucose of 45 to 80 mg/dL is considered normal, although this is dependent on a fairly normal range of serum glucose (70-120 mg/dL). Of greater usefulness is the CSF-to-serum glucose ratio because this is relatively constant through a wide range of serum glucose levels. The normal CSF-to-serum glucose ratio is 0.6 to 0.8; a ratio less than 0.5 is abnormal and should prompt urgent evaluation.

The principal causes of a reduced CSF-to-serum glucose ratio are listed in Table 32.3. Several infectious meningitides—bacterial, fungal, tuberculous, and spirochetal—are often heralded by hypoglycorrhachia. For instance, in one study of adults with bacterial meningitis, 70% had CSF glucose concentrations of less than 50 mg/dL. The CSF-to-serum glucose ratio in patients with bacterial meningitis is generally less than 0.33; a ratio of less than 0.23 in patients with acute meningitis had a positive predictive value of 99% for a bacterial etiology.

TABLE 32.3 Causes of Hypoglycorrhachia

Bacterial meningitis
CNS lymphoma
Fungal meningitis
Leptomeningeal carcinomatosis
Meningitis due to spirochetes (syphilis, Lyme)
Neurosarcoidosis
Tuberculous meningitis

Abbreviation: CNS, central nervous system.

Fungal meningitis is also associated with low CSF glucose—generally 20 to 40 mg/dL in one-half to two-thirds of patients. *M tuberculosis* meningitis characteristically depresses the CSF glucose; in one study of CSF culture-positive patients, the mean admission CSF glucose level was 23 mg/dL. Hypoglycorrhachia has also been reported in patients with Lyme disease and syphilitic meningitis, although the reduction in CSF glucose is often modest compared to cases of bacterial meningitis. The CSF glucose level in patients with viral meningitis is classically normal; that being said, rare cases of viral meningitis due to cytomegalovirus, paramyxoviruses, and lymphocytic choriomeningitis virus have been associated with low CSF glucose.

Other causes of hypoglycorrhachia include CNS lymphoma (approximately 10% of patients), leptomeningeal carcinomatosis (40% of patients), neurosarcoidosis (18% of patients), and lupus cerebritis/vasculitis (8% of patients). Patients with aneurysmal subarachnoid hemorrhage may have transient reductions in their CSF glucose (usually 4-8 d postictal). And finally, hypoglycorrhachia has been reported in patients who have received intrathecal injections of corticosteroids. Low levels of CSF glucose alone are not sufficient to make the diagnosis of ventriculitis or meningitis.

Cerebrospinal Fluid Findings in Inflammatory and Demyelinating Disorders

Although a detailed description of the CSF findings across the gamut of autoimmune and demyelinating neurologic disorders is beyond the scope of this chapter, there are certain CSF generalizations we can refer to. For instance, a mild lymphocytic pleocytosis and modest elevation in protein is frequently encountered in these patients. Approximately, one-third of patients with MS, optic neuritis, transverse myelitis, and even acute disseminated encephalomyelitis will have a mild lymphocytic pleocytosis. A greater proportion of patients with neurosarcoidosis and NMO will have a lymphocytic pleocytosis, and in the proper clinical context, a CSF pleocytosis of greater than 50 WBC/mm^3 or greater than 5 PMNs/mm^3 is strongly supportive of a diagnosis of NMO.

Even if the CSF cell count and protein are normal, evidence of an active intrathecal humoral immune response is often fundamental to the diagnosis of a neuroinflammatory disorder. During CNS inflammation, CSF IgG content may preferentially increase above serum levels, reflecting intrathecal synthesis. A routinely

TABLE 32.4 Cerebrospinal Fluid Cytology Yield

Type of CNS Malignancy	Percentage of Patients With Positive Cytology	Notes
Malignant glioma	7-66 (more than one sample)	
Parenchymal metastatic lesions	2-10	
Primary CNS lymphoma	16-26 (single sample)	Flow cytometry = higher yields EBV PCR as an adjunct in HIV+
Leptomeningeal carcinomatosis	47-92	41-71 with one sample; increasing yields with repeat sampling

Abbreviations: CNS, central nervous system; EBV, Epstein-Barr virus; PCR, polymerase chain reaction.

used estimate of intrathecal IgG synthesis is the IgG index, calculated as follows:

$$IgG\ index = \frac{IgG\ (CSF) \div IgG\ (serum)}{albumin\ (CSF) \div albumin\ (serum)}$$

An IgG index greater than 0.70 to 0.75 is often considered elevated (although parameters range depending on the clinical laboratory processing the sample). As an adjunct to the IgG index, the detection of unique oligoclonal bands (OCBs) within the CSF—distinct from those found in the serum—provides qualitative evidence of intrathecal Ig production. If two or more distinct CSF bands (bands absent from a corresponding serum sample) are detected, OCBs are considered to be positive. In MS patients, for instance, approximately 90% will have either an elevated IgG index or two or greater OCBs in the CSF, and these CSF findings may even precede a diagnosis of MS based on clinical history (or radiology) alone.

Cerebrospinal Fluid Cytology

Diagnosis of a CNS malignancy via CSF cytology is highly specific and relatively noninvasive (eg, compared to biopsy)—unfortunately, the sensitivity of CSF cytology ranges from low to moderate. Several factors may alter the yield of CSF cytology, including the site sampled (lumbar vs cisterna magna), the volume of CSF collected, the number of specimens examined, tumor location/grade, and the extent of leptomeningeal disease. The sensitivity of CSF cytology across CNS malignancies is outlined in Table 32.4. In general, repeated sampling will increase the yield of CSF cytology; for instance, in patients with leptomeningeal carcinomatosis, 41% to 71% will have a positive cytopathology on the first CSF sample, whereas 79% to 92% will have a positive cytology with repeated sampling. These findings form the basis for the recommendation that three large-volume (ideally >20 mL; >10 mL at the very least) LPs should be analyzed for malignant cells in patients with presumed leptomeningeal disease. Furthermore, CSF samples should be promptly delivered to the cytopathology laboratory for processing as autolysis begins within 1 to 2 hours of sample collection. In cases where primary CNS lymphoma is suspected, several additional CSF studies may aid in diagnosis. Immunophenotyping the CSF via flow cytometry can considerably increase the diagnostic yield by differentiating monoclonal B lymphocyte populations from reactive polyclonal lymphocytes even if the sample is relatively hypocellular. And in patients with HIV, CNS lymphoma is strongly associated with transformation of malignant cells by EBV; as such, EBV PCR in CSF has a high sensitivity and specificity for the diagnosis of CNS lymphoma in this particular patient population.

Precaution for Patients With Hemicraniectomy

For patients with malignant edema due to middle cerebral artery infarction and severe traumatic brain injury, hemicraniectomy can be life-saving. When patients who have history of hemicraniectomy waiting for cranioplasty (ie, still missing bone flap) present with altered mental status, it is important for clinicians to understand that unnecessary LP might lead to paradoxical herniation; atmospheric pressure may cause sunken sink syndrome to get worse and cause altered mental status, seizures, contralateral hemisensory or motor deficits and even coma.

Therefore, it is prudent to only proceed with LP when signs and symptoms of meningitis (fever, leukocytosis, somnolence, etc) are present rather than simply doing LP just to complete the workup or because of depressed alertness alone. When paradoxical herniation occurs due to LP in a patient with hemicraniectomy, one must keep the patient in Trendelenburg position, provide IV hydration and proceed with cranioplasty unless contraindicated.

Brain, Muscle, Nerve, and Skin Biopsy 33

John F. Crary, Thomas H. Brannagan III, and Kurenai Tanji

KEY POINTS

1. Morphologic categorization on the microscopic level of the disease by brain, muscle, and/or nerve biopsy, in conjunction with careful clinical and laboratory data assessment, remains relevant for diagnosis.
2. In the era of next generation gene sequencing, roles of tissue assessment through brain and neuromuscular biopsies are widening from conventional tissue diagnosis to assessment of specific genetic abnormalities, treatment effects, and clinical course and prognosis.
3. Less invasive skin biopsy is useful to assess the epidermal sensory nerve density and the autonomic innervation for a wide variety of systemic, or neurological diseases including neurodegenerative conditions such as α-synucleinopathy.

INTRODUCTION

Despite major advances in other diagnostic modalities, obtaining a tissue-based diagnosis through a biopsy of brain, muscle, or nerve remains an immensely powerful tool. Modern molecular and genetic techniques are increasingly being applied to biopsy specimens, greatly increasing their utility. Although widespread deployment of next-generation DNA and RNA sequencing technology has obviated the need for biopsy in some settings, these modern ancillary studies have not supplanted classical histomorphologic analysis. Biopsies are always performed in the context of an interdisciplinary team, which can include neurologists, internists, neuroradiologists, neurosurgeons, neurooncologists, and neuropathologists. To ensure appropriate assessment of the biopsy, a high level of communication between providers is of the utmost importance. Any potential benefits associated with having a tissue-based diagnosis must be balanced against the risks associated with the procedure. Brain biopsy is standard of care for brain tumors and has a high degree of utility in many other settings. Modern surgical techniques have helped to minimize complications and the probability of obtaining a nondiagnostic biopsy. In many contexts, the benefits of establishing a diagnosis and optimal treatment plan may outweigh the risks. Brain biopsy should always be a last resort, reserved for clinical settings where all other approaches have been exhausted. In this chapter, we provide an overview of the critical issues associated with the brain, muscle, and nerve biopsy. We also discuss the use of skin biopsies for epidermal nerve fiber density analysis.

BRAIN BIOPSY

Indications

Certain general considerations must be weighed before referring a patient for a brain biopsy. General risks associated with brain biopsy are similar to those associated with any surgical procedure, including deep vein thrombosis, postoperative hemorrhage, infection, etc. Patients on anticoagulant treatment might need to make adjustments given the risk of postoperative intracranial hemorrhage. Other complications include stroke, seizures, and cerebrospinal fluid (CSF) leak (fistula). Given the risks, it is generally accepted that all other diagnostic modalities must be exhausted before proceeding to brain biopsy.

An essential consideration prior to biopsy is determining the likelihood that the answer will lead to a change in patient management. Should, for example, the expected diagnoses have similar or no disease-modifying treatments, then the decision to proceed to a biopsy should be questioned. Furthermore, there is often a window of opportunity for the biopsy to be useful clinically. If the patient has deteriorated beyond the point to which a reasonable recovery in function can be anticipated, the biopsy might also be of limited value. Furthermore, the ability of the neuropathologist to recognize diagnostic features in the tissue is highest during the active phase of a disease. Once the pathology has run its course, secondary changes in the tissue can predominate and increase the likelihood of a nondiagnostic biopsy. Treatment effects, such as brain irradiation or steroids, may also mask diagnostic changes. For example, in a patient with a possible diagnosis of central nervous system (CNS) lymphoma, the use of systemic steroids should be deferred unless essential in the context of clinical care (ie, as a component of treating brain herniation) because treatment can make the biopsy nondiagnostic. Thus, it is essential that empiric treatments be used judiciously should a patient be a candidate for brain biopsy.

Brain biopsies have a prominent place in the treatment and management of CNS neoplasms. For mass lesions, partial brain resection and/or biopsy may be performed, depending on the functional importance of the region that contains the lesion. For malignant brain tumors, resections have the additional advantage of being both diagnostic and therapeutic in the form of debulking. Watchful waiting might be considered for benign brain tumors. Certain brain tumors in vital regions of the brain, such as brainstem gliomas, or eloquent cortical regions might not be amenable to a full resection, but guided stereotactic biopsy might be performed in some cases.

Brain biopsies are generally not required for most CNS infections because other forms of diagnosis are often definitive. For example, viral, bacterial, and fungal organisms can be identified with CSF sampling. In ambiguous contexts, a brain biopsy might be performed. Such biopsies are often of highest clinical use when two pathogenic processes with contradictory treatments are under consideration, for example, infectious versus autoimmune. Immunocompromised patients also provide a special setting where a broad differential diagnosis might trigger consideration of a brain biopsy.

In the case of age-related neurodegenerative disorders, brain biopsy is rarely performed. However, a biopsy may be considered in the setting of a rapidly progressive dementia, when there is

a reasonable chance that a treatable cause might be uncovered, which cannot be diagnosed by other means. Recent advances have led to the ability to diagnose specific autoimmune encephalitis through the detection of CSF autoantibodies. Moreover, CSF biomarkers and positron emission tomography scans have shown increasing use in diagnosing Alzheimer disease and prion disease. These advances have altered referral patterns, perhaps decreasing the total number of subjects undergoing brain biopsy for rapidly progressive dementia but increasing the diagnostic yield.

Brain biopsy is not indicated for ischemic stroke, but brain tissue may be sampled in the setting of hemorrhagic stroke to assess the vasculature for cerebral amyloid angiopathy. Vascular abnormalities may be resected surgically, and histopathologic analysis of such lesions is useful for differentiating arteriovenous malformations, cavernomas, and other lesions.

Brain Biopsy Requires an Interdisciplinary Approach

Brain biopsies are always performed in the context of an interdisciplinary team. The neurologist plays a critical role in clinical workup and referring patients to biopsy only when all other diagnostic modalities have been exhausted. Next, the neurologist will work closely with both the neuroradiologist and neurosurgeon to identify a radiographically evident lesion that is amenable to biopsy. Although "blind" biopsies of the nondominant (usually right) frontal cortex are often performed, targeting a specific lesion will most often provide the most informative results. If a biopsy is indicated, an open biopsy consisting of 1 cm^3 full-thickness specimen that contains gray matter, leptomeninges, and subcortical white matter is considered optimal. However, if the lesion is located within a vital or eloquent brain region, stereotactic core biopsies, sometimes measuring just a few millimeters, can provide diagnostic material.

During surgery, neurosurgeons often call on the neuropathologist to perform a *frozen section*. These intraoperative consultations are a means to rapidly obtain some diagnostic information and involve quickly freezing tissue, cutting on a cryostat, rapid hematoxylin and eosin (H&E) staining, and a preliminary diagnostic read by the pathologist. Although these tissue sections are of only limited diagnostic value, given the severe tissue freezing artifacts that develop (ie, interstitial and intracytoplasmic distortion from ice crystal formation), the assessment of the tissue architecture and cellularity provided can often place lesions in broad categories and may be helpful to guide intraoperative surgical decision making. Another use of the frozen section is confirming the presence of lesional tissue within the biopsy. Even with image-guided biopsies, small lesions may not be adequately represented. Performing a frozen section allows the team to sample additional tissues if necessary and greatly decreases the likelihood of a nondiagnostic biopsy. Critically, the preliminary diagnostic impression obtained through a frozen section must be interpreted with caution because it is not uncommon for revision following additional sampling and ancillary studies.

Neuropathologic Interpretation of the Brain Biopsy

Classical histopathologic examination by a neuropathologist remains the foundation of brain biopsy interpretation. Tissue sections from formalin-fixed brain are mounted on glass slides, stained with H&E for screening purposes, and examined microscopically. The H&E stain allows for visualization of the cytoarchitecture and all the cellular types in the brain, including neurons and glia. Other "special" stains are in routine use, including variations of the Bielschowsky silver stain, which is excellent for visualizing neuronal processes. Connective tissue stains such as trichrome, reticulin, or van Gieson are particularly useful for assessing vascular pathology. Congo red and thioflavin are useful for visualizing amyloid. Gram, Gömöri methenamine silver, and the Ziehl-Neelsen (acid-fast bacilli) stains are routinely used for microorganisms. While most pathology laboratories continue to rely on glass slides for their workflow, some have begun the transition to digital whole slide images. Once this happens more broadly, it is anticipated that we will begin to see more widespread deployment of machine learning algorithms (ie, computer vision) being applied in neuropathology, which will greatly increase the precision of many histologic tests.

Various ancillary studies are routinely used in neuropathology. Immunohistochemical stains, which rely on specific antisera to mark pathologic changes, are commonly employed in various contexts, particularly in the setting of neoplasms, where alterations can be detected with both diagnostic and prognostic relevance. Most molecular tests can be performed in fixed tissues, and it is no longer necessary to set aside frozen tissue for this purpose prior to processing. Should an infectious etiology be a consideration, tissue cultures are ideally performed using swabs of the surgical site, but fragments of fresh tissue can be submitted after surgery provided that it has not been fixed or contaminated. If lymphoma is a consideration, flow cytometry on fresh brain tissue can be performed to characterize the neoplastic population, but CNS lymphoma is most often of the diffuse large B-cell type, and these fragile cells generally do not perform well. Alternatively, neoplastic cells may be grown in culture for cytogenetic analysis. Electron microscopy is generally of only very limited use in the setting of brain biopsies. Next-generation DNA sequencing has become standard of care for most brain tumors for subclassification and targeted treatments, with IDH1/2 mutations, alongside ATRX loss and 1p/19q loss forming the foundation of the diffuse glioma classification scheme in the 2016 World Health Organization Classification of Tumors of the Central Nervous System. Also, next-generation sequencing can detect very low levels of pathogen DNA/RNA and may become more widely deployed in the future for this use.

MUSCLE BIOPSY

A muscle biopsy may be warranted when neurologic examination, laboratory tests, and electrophysiologic studies suggest a neuromuscular disease. Microscopic examination can help to distinguish between neurogenic and myogenic disorders and can also provide assistance in subclassifying myopathies and in rendering a specific diagnosis. With the advent of new genetic techniques including selective candidate gene sequencing, high-throughput sequencing of specialized gene panels, whole exome, and even whole genome sequencing, several genetic myopathies are diagnosed without invasive muscle biopsy. However, prior to embarking on exhaustive and often costly genetic investigations, a muscle biopsy chosen by thorough history taking and careful neurologic examination may provide an important aid in identifying the most likely cause of the disease that could be treatable. For example, the presence of widespread inflammation suggests

an acquired inflammatory myopathy as distinguished from other acquired or hereditary myopathies such as muscular dystrophy. Vasculitis and amyloidosis are often associated with a neuropathy, but both disorders may also be identified in muscle. Even with genetic investigations, morphologic categorization remains essential in some cases, especially when genetic abnormalities of unknown significance might complicate a diagnostic odyssey.

The decision to perform a muscle biopsy should also include noninvasive tools including blood test (eg, electrolytes, glucose, thyroid-stimulating hormone, vitamin D, creatine kinase [CK], and autoimmune screen), electrodiagnostic studies, and other laboratory tests. Imaging studies, such as magnetic resonance imaging (MRI), have been increasingly incorporated into the evaluation of muscle diseases. When combined with a biopsy, MRI can provide preoperative information about the muscle and adjacent structures (eg, fascia and subcutaneous tissue). In some cases, the MRI may disclose a characteristic pathologic involvement of muscle groups, which may lead directly to a genetic test and obviate the need for a biopsy.

The best muscles for biopsy are those moderately affected by the disease. MRI may be helpful in selecting a muscle that is most likely to provide diagnostic findings histologically. Severely atrophic muscles, prior injection, or electromyography examination sites, or previously traumatized muscles must be avoided. Patients with myoglobinuria or rhabdomyolysis should have the biopsy performed 6 to 8 weeks following the episode to allow muscle to recover from myonecrosis because extensive and active myonecrosis/regeneration on biopsy may obscure the underlying pathology. The most commonly investigated muscles are the deltoid, biceps, and vastus lateralis, when proximal weakness predominates. In patients with distal weakness, the anterior tibialis or gastrocnemius can be chosen depending on anterior or posterior predominance in weakness or atrophy. The clinical history should be available to the pathologist who examines the biopsy, to apply optimal histologic, histochemical, immunohistochemical, or electron microscopic techniques, to detect the important pathology in the tissue.

Technically, an accurate *morphologic diagnosis* requires formalin-fixed tissue to be processed for routine histology, rapidly and properly frozen tissue for histochemical and immunohistochemical preparations, and glutaraldehyde-fixed tissue for possible electron microscopic examination. Preserving a separate piece of snap frozen muscle is helpful for potential biochemical enzymatic assay(s) of glycogenolytic and glycolytic pathways; lipid metabolism; or mitochondrial respiration, electrophoresis for the protein expression study of muscle proteins, or genetic study.

When the routine histology of muscle demonstrates large or small groups of atrophic fibers, it is most suggestive of a *neurogenic disorder*. In contrast, *myopathic features* include a significantly increased fiber size, an increased number of internally nucleated fibers, necrotic and/or regenerating fibers, and abnormal intracytoplasmic storage material or inclusions. In chronic myopathies, notable endomysial fibrosis is often present. Inflammatory myopathies tend to display widespread, often multifocal, inflammatory infiltrates in the endomysium and/or perimysium. Recognizing certain immunocytologic and/or distribution patterns of inflammation may help subclassify the disease. The diagnosis of vasculitis, infectious or noninfectious granulomatous diseases, and amyloidosis can be established by routine histologic evaluation.

Histochemical staining techniques applied on cryosections help classify the fiber types (eg, myosin adenosine triphosphatase) and delineate cytologic abnormalities. A neurogenic disease can demonstrate fiber-type grouping and/or target/targetoid fibers, best demonstrated by myosin adenosine triphosphatase and nicotinamide adenine dinucleotide tetrazolium reductase, respectively. In certain myopathies, fiber-type predominance (eg, type 1 predominance in congenital myopathy) or selective fiber atrophy (eg, type 2 myofiber atrophy in steroid myopathy, critical illness myopathy, and collagen vascular disease) may occur. A variety of cytologic abnormality associated with myopathies, such as cores, nemaline (rods), tubular aggregates, caps, hyaline bodies, reduced bodies, cytoplasmic bodies, cytoplasmic mass, significantly increased mitochondria (ragged red fibers), excessive intracytoplasmic glycogen or lipid, and increased lysosomal reactivity with or without fiber vacuolation, are best characterized by proper histochemical preparations. Certain enzymatic deficiencies in metabolic myopathy can be histochemically demonstrated. These include myophosphorylase deficiency (glycogenosis type V), phosphofructokinase deficiency (type VII), myoadenylate deaminase deficiency, and cytochrome *c* oxidase (respiratory chain complex IV) deficiency (mitochondrial myopathy).

In the next-generation sequencing era, immunohistochemical staining using the antibodies against certain proteins may still offer an informative guide to select candidate gene(s) to be molecularly investigated. Genetic defects of dystrophin, sarcoglycan proteins, dysferlin, caveolin 3, emerin, merosin (α_2-laminin), collagen VI, carbohydrate side chain of α-dystroglycan, and others can be reliably tested in the tissue. When a muscular dystrophy demonstrates on biopsy morphologically indistinguishable abnormalities from those of other acquired myopathies, immunohistologic staining may help establish the cause of the disease. Furthermore, immunohistochemical detection of a specific protein deficiency may find the cause of otherwise nonspecific clinical symptoms in patients without typical dystrophic muscle weakness, such as persistent CK elevation (so-called benign hyperCKemia), myoglobulinuria/rhabdomyolysis, myalgia, or cramp. The other advantage of immunohistochemical staining is found in the analysis of inflammatory myopathies. The immunohistochemical detection of inflammatory markers (eg, major histocompatibility complex class I and II antigens, membrane attack complex) and immunocytologic typing of lymphocytic infiltrates may aid subclassification of immune-mediated inflammatory myopathies such as dermatomyositis, polymyositis, immune-mediated necrotizing myopathy, and inclusion body myositis.

In summary, to promptly establish an accurate and clinically meaningful diagnosis for patients with muscle disorders posing diagnostic challenges, it is essential to wisely minimize the number of investigations that could be extremely costly, especially under the increasing availability of commercial testing. Although next-generation sequencing methods face their own challenges including consent and interpretation of the sequenced data, traditional diagnostic methods such as muscle biopsy remain important tools in narrowing the differential diagnosis, in subclassifying the disease in a certain entity of disorders, in assessing the severity of disease, and in aiding the genetic alteration(s) of unknown significance to be properly interpreted.

NERVE BIOPSY

Nerve biopsy is indicated in patients with peripheral neuropathy when additional information about the etiology and severity of the disorder is needed. Although the options for biopsy sites are limited and the indications have generally decreased in the last

20 years, mostly due to increasing availability of molecular diagnostic testing for hereditary peripheral neuropathies and partly to various serologic autoantibody detection for dysimmune peripheral neuropathies, certain specific disorders require tissue diagnosis or characterization. These may include vasculitis; sarcoid neuropathy; amyloidosis; leprous neuropathy; chronic inflammatory demyelinating polyneuropathy, especially cases with clinically and/or electrophysiologically atypical and/or asymmetric presentation; neuropathy associated with monoclonal gammopathy; toxic neuropathy; storage disorders; and other systemic disorders with peripheral nervous system involvement. Several CNS diseases, for instance, metachromatic leukodystrophy, adrenoleukodystrophy, Krabbe disease, Lafora disease, neuronal lipofuscinosis, and other lysosomal storage diseases, may clinically involve the peripheral nerve. Nerve biopsy may also be helpful in identifying sporadic cases of genetically defined neuropathy or be required in the follow-up of patients with genetically diagnosed neuropathy with unusual clinical presentations. In children, the pathologically characteristic features in nerve may establish the diagnosis of giant axonal neuropathy and neuroaxonal dystrophy.

The sural nerve is the most widely studied nerve in health and disease and is generally recommended for biopsy. Motor nerve biopsy could be carried out for rare specific aims such as distinguishing motor neuropathies from motor neuron diseases. If mononeuritis multiplex clinically spares the sural nerve, another cutaneous nerve can be selected. For example, in most patients with suspected vasculitic neuropathy, a combined superficial fibular (peroneal) nerve/fibularis (peroneus) brevis muscle biopsy through a single incision on the lateral aspect of the leg is the most efficient and cost-effective procedure. For a comprehensive morphologic diagnosis, the removed nerve specimen is conventionally divided into three parts: buffered formalin-fixed for paraffin-embedded sections; buffered glutaraldehyde-fixed for epoxy resin sections, teasing fiber analysis, and electron microscopic assessment; and frozen for potential immunofluorescent study.

The routine histology of nerves demonstrates diagnostic features of vasculopathy (vasculitis, arteriolosclerosis, embolus, intravascular malignancy, etc), amyloid deposition, sarcoidosis, inflammation, infiltration of nerve by hematologic neoplasia, leprosy, giant axon neuropathy, and polyglucosan body disease. The hematologic neoplasia invading the nerve may be distinguished from reactive processes using immunocytologic lymphocytic markers. Immunoglobulin light-chain deposition secondary to plasma cell dyscrasia can be identifiable by in situ hybridization or by immunofluorescence study for kappa and lambda light chains. If a sizable amyloid deposit is histologically detected, the tissue may be useful for amyloid typing by mass spectroscopy. In general, however, most neuropathies do not show distinctive or specific morphologic findings in paraffin sections and usually require examination of semithin epoxy resin sections that are significantly thinner than paraffin sections, offering a better resolution of histology. Combined with observation of the teased myelinated fibers, axonopathy can be distinguished from demyelinating neuropathy. *Axonopathy* is recognized by marked depletion of nerve fibers associated with endoneurial fibrosis, with or without myelin debris or axonal regeneration. Teased fibers may exhibit prominent wallerian degeneration of myelinated fibers in an active phase of the disease. These axonopathic features can be seen in vasculitic neuropathy, toxic (iatrogenic) neuropathies, alcoholic neuropathy, amyloid neuropathy, and various neuropathies associated with metabolic disease, nutritional defect, and infectious disease. Segmental demyelination and remyelination, recognized in section as thinly myelinated fibers or onion bulb (concentric layers of Schwann cell processes) formation, are often the result of *primary demyelinating disorders* (eg, immune-mediated and inherited). The teasing fiber analysis may further illustrate myelin changes such as excessive myelin wrinkling and folding and tomacula formation (irregular thickening of myelin within internodes), and the semiquantitative analysis of those myelin alterations may be informative in identifying the presence of pathologic demyelinating condition because a low degree of myelin irregularity can be physiologically associated with aging.

Electron microscopic examination is useful to further delineate the pathology of axons, myelin, Schwann cells, or interstitial tissue (eg, accumulation of neurofilaments, organelles, or protein aggregation in axon; widened, uncompacted, or irregularly folded myelin lamellae; various intracellular inclusions or deposits) and is essential for the assessment of unmyelinated fibers.

For various autoimmune polyneuropathies, many serum autoantibodies directed against peripheral nerve glycoconjugate antigens have been identified as putative targets to date, and the direct *immunofluorescent study* using nerve frozen sections could be used to demonstrate possible immunoglobulin and compliment deposits within the myelin sheath. For example, intense and widespread deposits of the C3 component of complement and immunoglobulin M along the myelin sheath could help distinguish neuropathy associated with immunoglobulin M paraproteinemia from a morphologically or clinically resembling chronic inflammatory demyelinating polyneuropathy.

In summary, in the new genetic era, conventional nerve biopsy can still offer clinically useful information, when it is wisely chosen. However, it is noted that in various neuropathies with a multifocal nature or with proximal involvement such as plexuses and roots, findings in the nerve biopsy may not be representative of primary pathology taking place at other sites of the nerve and that the diagnostic usefulness of nerve biopsy must be assessed on a case-by-case basis.

SKIN BIOPSY

Skin biopsy is primarily used to evaluate cutaneous sensory and autonomic nerves, and clinically, it has been widely used as a useful diagnostic tool for acquired and hereditary small-fiber neuropathy by the quantification of *intraepidermal nerve fiber density* (IENFD). The clinical course of certain systemic autoimmune diseases including celiac disease, Sjögren syndrome, and certain channelopathies may be complicated by small-fiber symptoms. Skin biopsy has also been used in detection of other neuropathies such as small fiber–predominant polyneuropathy and distal symmetric neuropathy. Given the minimally invasive nature, it enables multiple sampling from different biopsy sites (eg, proximal and distal sites in a same limb of the patient) for distinguishing non–length-dependent neuropathies (eg, ganglionopathies, multifocal involvement of nerve) from the length-dependent and for comparison or monitoring patients over the clinical course. For IENFD analysis, epidermal axons are immunohistochemically visualized in the tissue sections, commonly using the antibody against a panaxonal marker, PGP9.5 (an ubiquitin hydrolase: a major protein of nerve cells including axons and dendrites), and are counted in a given length of the epidermis. The quantitative analysis of nerve fibers requires normative values, and in patients with small-fiber neuropathy,

the IENFD tends to be significantly low. Morphologic abnormalities in the epidermal axons (eg, short length, small diameters, swelling, and complicated branching patterns) may precede the actual dropout of the epidermal axons. The limitations of skin biopsy include the following: (1) Skin biopsy rarely provide the specific differentiation of pathogenic mechanism/cause of the disease, and (2) except in a clinical trial setting, the observation of skin biopsy rarely changes clinical management especially in diseases where the cause of neuropathy is already known. Skin biopsy can be used also for evaluation of patients with autonomic disorders such as diabetes, impaired glucose tolerance, chemotherapy-induced autonomic neuropathy, and connective tissue disorders. Furthermore, autonomic dysfunctions in neurodegenerative disorders could be assessed by semiquantification of the autonomic innervation to sweat glands or arrector pili muscle. In particular, recent studies of α-synuclein intraneural deposition in sudomotor and pili motor nerve have demonstrated high specificity with variable sensitivity, raising the possibility that the analysis of α-synuclein in relatively noninvasive skin biopsy could serve as a possible biomarker of synucleinopathy including Parkinson disease for a prompt and effective treatment by early detection of the disease at prodromal stages. However, reliability and correlation with neuropathy/autonomic function scores have been debatable in variable published methods that have not been as yet optimized and standardized, and availability of normative values is limited.

In summary, skin biopsy is a unique minimally invasive biopsy technique, and the quantification of IENFD remains a reliable diagnostic tool for small-fiber neuropathy, with high diagnostic specificity and relatively good sensitivity, which cannot be readily detected by nerve conduction study. Indications of skin biopsy are expanding, with potential use as biomarkers of certain neurologic diseases for effective treatment and management of neurologic diseases involving small nerve fibers.

34 Intracranial Pressure and Neurocritical Care Monitoring

Charles L. Francoeur and Stephan A. Mayer

KEY POINTS

1. Intracranial pressure monitoring is indicated in comatose patients (noncommand following) who have evidence of abnormal intracranial mass effect on computed tomography and a prognosis that merits aggressive intervention.
2. External ventricular drains can be used to treat intracranial hypertension via cerebrospinal fluid drainage and are also capable of measuring intracranial pressure.
3. Continuous electroencephalography monitoring can detect nonconvulsive seizures or status epilepticus in 10% to 30% of comatose intensive care unit patients.

INTRODUCTION

Monitoring plays a fundamental role in the daily practice of neurocritical care. Bedside neuromonitoring supplements clinical evaluation and imaging with the underlying goal of detecting physiologic derangements before neurologic deterioration and irreversible damage occurs. This chapter introduces continuous bedside neuromonitoring modalities that are in use in the most advanced neurocritical care units around the world. Although no study has tested whether "multimodality" monitoring improves outcomes, these advanced systems allow for recognition of real-time pathologic events that we were unable to identify just a few years ago and provide new insights into the complex pathophysiology of severe brain injury.

INTRACRANIAL PRESSURE AND CEREBRAL PERFUSION PRESSURE MONITORING

Physiologic Principles

Intracranial Pressure

The rigid skull is filled with incompressible content, namely brain (1,400 mL), cerebrospinal fluid (CSF) (150 mL), and blood (75 mL). In normal state, with blood outflow being equal to blood inflow, CSF absorption equals CSF production (~20 mL/h) and intracranial pressure (ICP) lies between 5 and 15 mm Hg in the supine position (8-20 cm H_2O).

As described in the Monro-Kellie model, if any one of those compartments increases in volume, as in the case of obstructive hydrocephalus, or a new mass lesion is added (a subdural hematoma for example), buffering mechanisms are called upon. The first adaptive process is egress of CSF in the spinal canal, provided there is no obstruction to flow. The second step is shifting of blood from the capacitance vessels (veins) out of the intracranial compartment. Once these buffering mechanisms are exhausted, intracranial compliance is reduced and ICP quickly rises (Fig. 34.1).

Secondary neurologic injury occurs with ICP over 20 mm Hg, and elevated ICP above this threshold after traumatic brain injury (TBI) or subarachnoid hemorrhage (SAH) correlates with increased mortality. Initially, cerebral blood flow (CBF) is reduced, causing ischemia, a problem exacerbated by loss of cerebral autoregulation. At this point, level of consciousness may decrease. The most dramatic clinical signs related to ICP elevation, such as an unreactive "blown" pupil and motor posturing, are produced by ICP gradients within the cranial vault, which lead to brain tissue shifting and herniation. In these cases, initial regional CBF reduction will be compounded by vascular compression in later stages of herniation, inducing secondary territorial infarcts of the anterior or posterior cerebral artery.

Numerous ICP treatment thresholds have been proposed in the literature, ranging from 15 to 35 mm Hg, including in the latest Brain Trauma Foundation guidelines, which suggest maintaining ICP below 22 mm Hg. The relationship of ICP to outcome is complex. Although the evidence suggests a clear relationship with mortality, most studies have found only a weak or no association between intracranial hypertension and morbidity. We also know from multimodal monitoring that some patients with mildly elevated ICP show no dysfunction of brain energy metabolism and that the reverse is also true (ie, patients with normal ICP values can have highly dysfunctional energy metabolism).

FIGURE 34.1 Compliance is the change in pressure per change in unit of volume ($\Delta P/\Delta V$). Once compensatory mechanisms are overwhelmed, compliance dramatically decreases, meaning that with a smaller increment in intracranial volume, a much more dramatic increase in pressure develops. Abbreviation: ICP, intracranial pressure.

FIGURE 34.2 Intracranial pressure waveform. *P1*, the percussive wave, comes from arterial transmission through the choroid plexus. *P2*, the tidal wave, reflects brain tissue elastance. As it rises, so does *P2*. When *P2* exceeds *P1*, it has an excellent sensitivity to predict incoming increase in intracranial pressure. The third and final wave (*P3*) is secondary to aortic valve closure, a corollary of the arterial dicrotic notch.

The underlying concept behind brain multimodality monitoring is to move away from generalized treatment thresholds and toward individualized ICP treatment thresholds that may vary over time and with clinical context.

Waveforms

Mean ICP is a time average of the ICP waveform. The latter consists of three components, in order of frequency: (1) the pulse pressure waveforms, (2) the respiratory waveforms (0.1-0.3 Hz) associated with the respiratory cycle, and (3) the slow vasogenic waveforms (eg, "Lundberg A and B waves"). The pulse pressure waveform presents deflections that correspond to transient increases in cerebral blood volume with each systole that are divided into three waves (**Fig. 34.2**): an initial percussion wave, which occurs at the start of systole and under normal conditions is of greatest amplitude (called *P1*); a secondary tidal wave then occurs, which reflects brain recoil or elastance (*P2*); followed by a third dicrotic wave created by closure of the aortic valve at the start of diastole (*P3*). In states of reduced intracranial compliance, the pulse pressure amplitude typically increases and P2 component exceeds P1 in the waveform display, as the "shock" of systolic inflow becomes less absorbable.

Slow vasogenic waveforms are not only less specific but also present typical patterns in cases of low cerebral compliance, where pathologic waveforms may occur. Lundberg A waves (or plateau waves) are prolonged periods (5-20 min) of sharp rise in ICP (>20 mm Hg) (**Fig. 34.3**). They are caused by sustained vasodilation and abruptly occur when either cerebral perfusion pressure (CPP) or intracranial compliance is low (see **Fig. 111.4**). Severe plateau waves preceding the onset of brain death can last for hours and reach levels as high as 50 to 100 mm Hg. Lundberg B waves are shorter duration (<10 min), clustered and cyclic (0.01-0.05 Hz), low-amplitude elevations (<20 mm Hg) that indicate that intracranial compliance is compromised, although they are sometimes observed in nonpathologic states.

Cerebral Perfusion Pressure and Pressure Reactivity

Arterial blood carries oxygen and glucose, which are necessary for neuronal function and survival. CPP, defined as the difference between mean arterial pressure (MAP) and ICP, is the main determinant of CBF.

$$CPP = MAP - ICP$$

FIGURE 34.3 Lundberg A (plateau) wave, with characteristic "mirror" reduction in cerebral perfusion pressure (CPP). The plateau wave is terminated by an infusion of dopamine, which leads to an elevation in mean arterial pressure and reversal of the brain's vasodilated state. Abbreviations: ICP, intracranial pressure; MAP, mean arterial pressure.

Adequate comprehension of CPP physiology requires an understanding of cerebrovascular pressure reactivity, which is the intrinsic capacity of the cerebral vasculature to adapt to changing pressure and maintain constant CBF by varying the caliber of its resistance vessels at the precapillary level. In healthy individuals, this mechanism allows for a stable level of CBF across a wide range of MAP (40-160 mm Hg). In pathologic states, however, autoregulation often fails and CBF becomes pressure passive, putting the brain at risk for both ischemia or hyperemia. Cerebral autoregulation can also be affected by extrinsic factors such as pH, temperature, and drugs.

Accurate measurement of CPP requires the same zero reference point for both arterial blood pressure and ICP, that is, using the tragus of the ear as the external landmark. Head elevation with the zero reference point at the tragus for ICP and at heart level for MAP induces a significant overestimation (up to >10 mm Hg) of CPP, which can put the brain at risk for hypoperfusion and ischemia.

The usually accepted critical autoregulatory threshold exposing patients to risk of cerebral ischemia is below 50 mm Hg (**Fig. 34.4**). Optimal CPP values are, however, more elusive. Recommended targets are usually between 60 and 70 mm Hg, based on low-quality evidence. It is plausible that optimal values vary both across individuals, pathologies, and within a patient's clinical evolution. Some experts advocate different treatment approaches, and hence different targets, according to the presence or absence of an intact pressure reactivity.

Pressure Reactivity Indices

The potential benefit associated with monitoring pressure autoregulation is to individualize and thereby optimize CPP. A surrogate measure of pressure autoregulation is the correlation

FIGURE 34.4 Autoregulation allows for a constant cerebral blood flow in the face of changing cerebral perfusion pressure (CPP) by varying vascular caliber *(red line)*. Over the limit of around 150 mm Hg of CPP in a healthy brain, there is endothelial injury and blood-brain barrier disruption with luxury perfusion and edema formation. Under 50 mm Hg of CPP, vasodilatation is maximal and cerebral blood flow (CBF) becomes directly proportional to CPP with great risks of hypoperfusion. Both hyperemia and reactive vasodilation can increase intracranial pressure (ICP) when intracranial compliance is reduced *(green line)*. With vasodilatory cascade physiology (*shaded blue*), vasodilation in response to low CPP drives up cerebral blood volume ICP. With perfusion pressure breakthrough physiology *(shaded orange)*, vasodilation from hydrostatic forces increases cerebral blood volume and ICP.

between MAP and ICP because they are physiologically interconnected. Many methods have been described to assess this relationship. An example of static measurements is with the manipulation of mean arterial pressure (MAP), commonly following the administration of drugs, such as a bolus of norepinephrine. If pressure reactivity is intact, a significant MAP rise will be accompanied by a decreased ICP due to vasoconstriction. If autoregulation is failing, a rise in MAP will cause an increase in ICP due to pressure-passive vasodilation. The most studied and best validated method to assess autoregulation is a continuous real-time measurement coined PRx (pressure reactivity index). It is calculated using high-frequency sampling (50 Hz) of the MAP and ICP to create a moving correlation coefficient from 30 consecutive 10-second averages of the MAP and ICP waveforms. The linear correlation coefficient points produces a PRx value between −1.0 and +1.0. Where negative or close to zero, autoregulation is intact. A positive value, however, implies a failing autoregulation. PRx can then be plotted against CPP, which under normal conditions shows a U-shaped curve. Published data support the concept of targeting CPP at the point where PRx is most negative and autoregulation is most intact (CPP_{opt}; **Fig. 34.5**). To obtain such a continuous, validated, high-resolution and real-time index, one must use specialized software such as Intensive Care Monitoring (ICM+; University of Cambridge, England, United Kingdom) or a similar alternative

External Ventricular Drainage

Since the landmark study published by Lundberg in 1960, external ventricular drainage (EVD) has been the gold standard for ICP monitoring. It consists of a catheter blindly inserted into the lateral ventricle and connected via fluid-filled tubing to an external pressure transducer. The insertion is usually on the nondominant side just anterior to the coronal suture roughly in the midpupillary line approximately 6 cm deep, although other approaches are described. The fluid-filled system relays the pulsatile waveform to a transducer, which is then converted to a digital signal. The ICP number displayed at the bedside represents the mean pressure. The hydrostatic reference point is the foramen of Monro, which is estimated using the external acoustic meatus or the tragus.

EVD placement has the advantage of allowing therapeutic CSF drainage, making it the monitoring of choice in case of

FIGURE 34.5 Pressure reactivity index (PRx, *black line*) and brain tissue oxygen tension ($PbtO_2$, *gray line*) as a function of cerebral perfusion pressure (CPP) in a patient with poor-grade subarachnoid hemorrhage. *Arrow* denotes the point of optimal autoregulation (CPP_{opt}) at 90 mm Hg, corresponding to the lowest values of PRx. Note that this also corresponds to the highest levels of $PbtO_2$ and that $PbtO_2$ values fall progressively as CPP drops from 90 to 55 mm Hg.

elevated ICP secondary to hydrocephalus. Depending on the indication, height of the EVD drip chamber is kept from 0 to 20 cm above the tragus, with lower levels causing a higher hourly CSF drainage rate. With a conventional EVD system, either ICP can be monitored with the system clamped or CSF can be drained but not both at the same time. Some EVD systems are equipped with a fiber-optic pressure transducer at the tip, which allows for simultaneous pressure monitoring and CSF drainage.

The main complications of EVD placements are bleeding and infection. Clinically significant (requiring intervention) bleeding rates are 1% or less, but the risk of infection (ventriculitis) ranges from 5% to 15%. As for any other invasive devices, aseptic insertion technique, limited manipulations, avoidance of routine CSF sampling, and quick removal are the best ways to keep infectious complications to a minimum.

Safe discontinuation of an EVD is accomplished by performing a 24-hour clamp trial. If the ICP remains below 20 mm Hg, the patient remains stable, and a follow-up computed tomography (CT) shows no interval ventricular enlargement, the EVD can be safely removed.

Intraparenchymal Intracranial Pressure Monitors

Intraparenchymal devices are now the most commonly used method of ICP monitoring, and they are as reliable and accurate as EVD. In most systems, a fiber-optic or strain gauge pressure transducer is located at the catheter tip, which is inserted 1 to 3 cm into the cerebral parenchyma. Although often placed on the nondominant side, insertion should be ipsilateral to the lesion aiming for the brain parenchyma most at risk for secondary injury. The risk of insertional bleeding with a parenchymal ICP monitor is lower than that of an EVD, and the risk of infection is negligible. Displacement or breakage is the most commonly observed technical complication. Although drift (ie, loss of accuracy over monitoring time) is well described with strain gauge devices, it is rare with fiber-optic ones. The main challenge in interpretation stems from the basic assumption that the ICP read at one point properly reflects the average pressure throughout the intracranial system.

Indications for Intracranial Pressure Monitoring

As a general rule, indications for the placement of an EVD or ICP monitor are as follows:

1. The patient is comatose (generally Glasgow Coma Scale score ≤8).
2. Brain imaging indicates that the patient is at risk for elevated ICP due to the presence of significant intracranial mass effect.
3. Aggressive intensive care unit (ICU) care is warranted.

The Brain Trauma Foundation issued updated recommendations in 2015 regarding indications for ICP monitoring of severe TBI patients (Table 34.1). Other considerations include when clinical exam is likely to be lost for a moderate to a long period of time, especially if associated with physiologic derangement, for example, during major surgery or a difficult to ventilate acute respiratory distress syndrome patient. Obstructive hydrocephalus is also a clear indication for EVD insertion. Recent guidelines from the International Multidisciplinary Consensus Conference on Multimodality issued recommendations for ICP monitoring in non-TBI patients (Table 34.2). Examples given in the consensus include intracerebral and SAH, massive ischemic stroke, meningitis, hypoxic-ischemic injury, and fulminant hepatic failure. Any pathology complicated by elevated ICP might benefit of such monitoring when clinical exam is not trustworthy because it allows optimization of cerebral hemodynamics through CPP manipulation, aggressive ICP treatment, as well as detection of new catastrophic events.

TABLE 34.1 Indications for Intracranial Pressure Monitoring in TBI Patients[a]

Level of Evidence	Indication
Level I and II A	There is insufficient evidence to support a level I or II A recommendation for this topic.
Level II B	Management of severe TBI patients using information from ICP monitoring is recommended to reduce in-hospital and 2-wk postinjury mortality.

Abbreviations: ICP, intracranial pressure; TBI, traumatic brain injury.

BRAIN OXYGENATION MONITORING

Physiologic Principles

The human brain, composing 2% of our body weight, consumes 20% of total body oxygen. Approximately, 90% of the energy is used by neurons mainly for synaptic activity and to preserve ionic gradients. The energy substrate is high-energy adenosine triphosphate (ATP) produced from glucose through aerobic metabolism. In the absence of continuous oxygen delivery, ATP production ceases within seconds. Osmotic gradients are lost, edema sets in, intracellular calcium rises, and early apoptotic mechanisms are triggered. Specific monitoring allows for early detection and reversal of brain hypoxia in the neuro-ICU. Two invasive bedside techniques are described: *brain tissue oxygen partial pressure* ($PbtO_2$) and *jugular venous oxygen saturation* ($SjvO_2$) monitoring.

Both $SjvO_2$ and $PbtO_2$ are dependent on CBF, arterial oxygen content, and the cerebral metabolic rate of oxygen consumption

TABLE 34.2 Indications for Intracranial Pressure Monitoring in Non-TBI Patients

Level of Evidence	Indication
Moderate	Patients at high risk or those with clinical or radiologic evidence of acute symptomatic hydrocephalus
Low	SAH, ICH, and other non-TBI conditions in patients at risk for elevated ICP based on clinical and/or imaging features
Low	All poor-grade SAH patients with consideration for multimodality monitoring
Low	Patients who undergo hemicraniectomy in the setting of cerebral edema

Abbreviations: ICH, intracerebral hemorrhage; ICP, intracranial pressure; SAH, subarachnoid hemorrhage; TBI, traumatic brain injury.

($CMRO_2$). $AVDO_2$, the arteriovenous difference in oxygen content, can be simplified as $SaO_2 - SjvO_2$ because other parameters, such as hemoglobin, remain constant during cerebral transit.

$$CMRO_2 = CBF \times AVDO_2, \text{ where } AVDO_2 \approx SaO_2 - SjvO_2$$

Low $PbtO_2$ values are often seen in severe neurologic injuries despite normal ICP and CPP values. Imaging cannot reliably predict brain tissue hypoxia because some episodes result from cellular distress and increased oxygen demand related to seizures, shivering, or other hypermetabolic states.

Available data strongly suggest an independent association of the burden of brain tissue hypoxia with poor outcome both in TBI and SAH patients. Taken together, these findings underline the rationale for incorporating invasive brain oxygenation monitoring as a management option for life-threatening brain injury. Use of either $SjvO_2$ or $PbtO_2$ monitoring is recommended for patients at risk for cerebral ischemia according to the latest International Multidisciplinary Consensus Conference on Multimodality Monitoring.

Jugular Venous Oxygen Saturation Monitoring

This technique employs continuous oximetry in the jugular bulb to analyze oxygen content of cerebral venous drainage. The six major cranial sinuses, running between the dura mater and the cranial periosteum, end up forming the left and right internal jugular veins (IJV). The IJV starts with the jugular bulb, a small dilation at the jugular foramen, into which the cerebral hemispheres, the cerebellum, and the brainstem drain. Venous blood from extracranial sources make up less than 5% of net blood flow in the jugular bulb. Sampling necessitates retrograde placement of a catheter in the IJV up to the bulb. The tip of the catheter, verified with a lateral or anteroposterior x-ray, should lie at the level of the mastoid bone above the lower border of C1.

Normal $SjvO_2$ values range between 55% and 75%. Low values suggest insufficient oxygen delivery to the brain to meet metabolic needs, which may reflect either high cerebral oxygen consumption, low CBF, or both. Values under 45% are associated with cellular dysfunction. One limitation of $SjvO_2$ is that it reflects global oxygenation; regional ischemia can be missed. It has been estimated that 13% of the brain volume must be ischemic to impact on $SjvO_2$. Another technical point is that improper catheter placement will mean a greater contamination by extracranial blood reducing sensitivity to detect brain hypoxia. $SjvO_2$ values above 75% suggest either hyperemia from loss of autoregulation resulting in excessive cerebral vasodilation or low oxygen consumption.

Brain Tissue Oxygen Pressure Monitoring

The most commonly used technologies for $PbtO_2$ measurement today are based on use of a Clark electrode (Licox) and oxygen quenching methods using a microchip at the catheter tip (Raumedic). The Clark electrode has two metallic electrodes surrounded by electrolytes and a membrane. Oxygen from the interstitial space diffuses through the membrane and is reduced at the cathode, which changes the voltage difference between the two electrodes. The more oxygen, the more the voltage change measured. The oxygen quenching method uses a lanthanide polymeric matrix that luminesces at different wavelengths based on regional oxygen tension. A fiber-optic cable detects these wavelengths and transmits a continuous output signal.

TABLE 34.3 Brain Tissue Oxygen Partial Pressure Thresholds (Clark Electrode Technology)

$PbtO_2$ Value (mm Hg)	Interpretation
>50	Hyperemia or inability to extract O_2
25-50	Normal
<20	Hypoxia
<10	Severe hypoxia

Abbreviations: O_2, oxygen; $PbtO_2$, brain tissue oxygen partial pressure.

The tip of the probe should be located in the white matter, where normal $PbtO_2$ levels range from 25 to 50 mm Hg (Table 34.3). A postinsertion CT scan is mandatory to confirm positioning and interpret readings because placement in hemorrhagic or infarcted tissue results in uninterpretable readings near zero. An equilibration period of 60 minutes is expected, and an oxygen challenge (5 min 100% fraction of inspired oxygen) is performed daily to make sure of the proper monitor functioning: It should lead to a threefold $PbtO_2$ increase, provided CBF is adequate.

The volume of brain tissue sampled with this focal form of monitoring ranges from 15 to 20 mm^3. As with ICP monitoring, the area of probe insertion should be carefully considered; areas most at risk for secondary injury are the best target. An example would be in the vascular territory of the ruptured aneurysm, which is at highest risk for developing delayed cerebral ischemia (DCI).

$PbtO_2$ measured with different technologies are not interchangeable, and the most cited values come from data obtained with Clark electrode technology (see Table 34.3). Values with the oxygen quenching systems tend to run higher.

$PbtO_2$ monitoring is an adjunct to ICP monitoring in comatose patients. A low $PbtO_2$ can help detect a new critical event, such as vasospasm after SAH or a seizure. A reassuring value, on the contrary, may be an argument for permissive ICP management. $PbtO_2$ changes are a way to evaluate the patient's response to DCI treatment with hemodynamic augmentation therapy. It can also be used to carefully titrate aggressive hyperventilation therapy or to detect a detrimental ventilation strategy. Some observational studies suggest that combining ICP/CPP and $PbtO_2$-based management leads to better outcomes in TBI or SAH patients. A recent pilot clinical trial gave an interesting signal that PbO_2-based management of severe TBI patients is both feasible and might lead to better outcomes than ICP-only management. A phase III trial testing this hypothesis (BOOST-3) is now underway.

Near-Infrared Spectroscopy

Cerebral oximetry monitoring systems allow continuous, real-time, noninvasive measurement of regional cortical oxygen saturation, a reflection of the balance between oxygen delivery and utilization that has been shown to correlate well with jugular venous bulb saturation and brain tissue oxygen pressure. Based on near-infrared spectroscopy, it relies on multiple wavelengths in the near-infrared range (ie, 680-900 nm) to discriminate between the unique absorption spectra of oxyhemoglobin and deoxyhemoglobin. Sensors with an integrated light source and photodetector are applied to each side of the forehead and the cerebral tissue sampling volume is estimated to be 1.5 mL.

Unfortunately, there is a lack of standardization between commercially available near-infrared spectroscopy devices, and significant differences exist in how they respond to changes in oxygen saturation. Clinical studies suggest that it is reliable in detecting perioperative cerebral oxygen desaturation events, especially in cardiac surgery. Although promising in the ICU environment and in the neurocritical care population, data is still limited. Threshold regional cortical saturation values associated with poor outcomes or that should trigger intervention are poorly defined, although <50% is probably a reasonable limit to detect serious events.

CEREBRAL BLOOD FLOW MONITORING

Physiologic Principles

Adequate CBF is critical to proper function and survival of neurons, and hence, avoidance of hypoperfusion is essential to limit secondary injury (see Fig. 34.4). Precise regulation of CBF at a constant level involves numerous overlapping mechanisms globally named autoregulation, of which pressure reactivity described earlier is a component, and which also includes reactivity to arterial oxygen and carbon dioxide (CO_2), neurovascular coupling, and autonomic control.

The cerebral vessels are highly sensitive to variations in the P_{CO_2}, a feature unique to cerebrovasculature. However, a long-standing question has been whether Pa_{CO_2} or pH is the main driver of autoregulation. It appears that vessel caliber is mediated by extracellular pH levels, with lower pH (acidosis) values leading to dilation and higher pH (alkalosis) to constriction. However, CO_2 molecules diffuse readily across the cerebral blood-brain barrier, inducing changes in pH, which is not the case of intravascular buffers such as bicarbonate. The point is that alterations in alveolar gas exchange elicit immediate changes in CBF, but they are short-lived (approximately 6 h) as a changes in CSF and extracellular bicarbonate concentration and correction of extracellular pH by glial cells will ensue. From a clinical standpoint, hyperventilation will reduce CBF significantly enough to aggravate ischemia in an already injured brain, and hypoventilation can augment cerebral blood volume significantly enough to worsen existing intracranial hypertension.

Hypoxia will reduce cerebrovascular smooth muscle tone and increase CBF when the arterial content of oxygen reaches a threshold at the steep portion of the oxyhemoglobin dissociation curve (<80% arterial saturation of oxygen or, a Pa_{O_2} of 50 mm Hg) (see Chapter 111). Neurovascular coupling is another broad mechanism of autoregulation allowing local cerebral metabolism to be tightly associated to local brain perfusion. Autonomic regulation also appears to play a significant role in regulating CBF. All these mechanisms are redundant and synergistic with various interactions. For example, loss of pressure reactivity doesn't preclude sensitivity to changes in pH. Significant hypotension, however, may abolish cerebrovascular reactivity to CO_2.

Continuous Cerebral Blood Flow Monitoring

These examples stress the importance of direct and valid CBF monitoring to detect hypoperfusion before it leads to irreversible ischemia and while it is still amenable to treatment. Modern imaging techniques such as positron emission tomography and CT perfusion allow detailed information about cerebral hemodynamics to be obtained but are unable to provide continuous data for clinical monitoring at the bedside.

Thermal Diffusion Flowmetry

Thermal diffusion flowmetry is an invasive technique that allows continuous quantitative measurement of regional cerebral blood flow (rCBF) measured in mL/100 g/min. The probe is inserted 25 mm into the brain and comprises a thermistor at the tip and a temperature sensor a few millimeters proximal. Tiny temperature fluctuations are produced by transiently heating the thermistor tip; according to the Fick principle, the resulting change in temperature at the proximal sensor is inversely related to CBF.

Real-time dynamic rCBF data have been correlated with xenon CT perfusion studies and Pbt_{O_2} monitoring. Studies relating rCBF to outcomes are limited. Because the probe is located in the subcortical white matter, 15 mL/100 g/min is a reasonable threshold for defining critical hypoperfusion. Low CBF values alone, however, do not necessarily imply active ischemia because low CBF can also be coupled to a low rate of cerebral metabolism. Concurrent Pbt_{O_2} or Sjv_{O_2} monitoring is helpful in differentiating low CBF states.

One of the main limitations of thermal diffusion flowmetry is its focal nature; the data is highly dependent on the probe's location. Other technical limitation is the 5-minute recalibrations that occur every 30 minutes during which monitoring is unavailable. Infectious and bleeding complications are well under 1%.

CEREBRAL MICRODIALYSIS

Physiologic Principles

Key elements to the pathophysiology of brain injury and ischemia that can be monitored include (1) energy substrates (glucose), (2) brain glucose metabolism products (lactate, pyruvate), (3) excitatory neurotransmitters (glutamate), and (4) products of cell membrane degeneration (glycerol). Brain energetic function relies on glucose metabolism to pyruvate, which then enters the Krebs cycle to produce a total of 38 moles of ATP per mole of glucose. This process is contingent on oxygen availability. Hypoxia will lead to anaerobic metabolism, where pyruvate is metabolized into lactate, a much less efficient energy-producing pathway with a yield of only 2 moles of ATP per mole of glucose. Lactate can be used as a source of energy production by neurons when glucose is unavailable. If the entire glycolysis process is accelerated, for example, in the presence of catecholamines or fever, both pyruvate and lactate will be elevated. If hypoxemia is present, only lactate will increase, as pyruvate is anaerobically consumed with lactate as an end product. This is the logic behind the use of lactate-to-pyruvate ratio (LPR) to detect anaerobic metabolism, an important physiologic marker of ischemia (Fig. 34.6).

Another important mechanism of neuronal injury is excitotoxicity. Glutamate is the main excitatory amino acid, and levels are kept low by astrocytes responsible for converting glutamate back to glutamine. This is an energy-dependent process and metabolic failure will lead to elevated glutamate levels. This will mediate excessive intracellular calcium influx and neuronal damage.

When cellular metabolism fails, one of the final common pathways is loss of cellular integrity and membrane degradation.

FIGURE 34.6 Efficient adenosine triphosphate (ATP) production from glucose necessitates oxygen (O_2). Without O_2 or if the cells are unable to use it, the pathway shifts to lactate production.

Release of phospholipids ensues, which are converted to free fatty acids and glycerol. This makes glycerol a marker of advanced cellular damage.

Microdialysis Monitoring

Microdialysis allows bedside semicontinuous analysis of the chemical composition of the brain interstitial fluid. The probe is a 0.6-mm double-lumen catheter with a semipermeable membrane that permits free diffusion of water and solutes down their concentration gradient. Isotonic fluid is perfused at a constant rate of 0.3 μL/min and the perfusate is collected and analyzed hourly. The probe is usually 2 cm deep, close to white matter.

The commercially available biomarkers for clinical use are lactate, pyruvate, glucose, glycerol, and glutamate (**Table 34.4**). One of the most clinically useful indices is the LPR. Values over 20 to 25 correlates with worse outcomes in TBI and SAH patients, and a ratio over 40 is used to define "metabolic distress." LPR elevation can be further defined as a type I or II depending on trends in pyruvate levels. Type I LPR elevation is present when pyruvate is decreased with a marked increase in lactate; it is attributed to a lack of oxygen. In type II, pyruvate is normal or elevated indicating mitochondrial failure and a normal supply of metabolic substrates.

Low brain glucose levels (normally 1-2 mmol/L) are also related to outcome in SAH and TBI patients, especially when less than 0.50 mmol/L. An LPR ratio greater than 40 combined with a brain interstitial glucose level less than 0.5 mmol/L is termed *metabolic crisis* and is associated with poor outcomes and a high risk of death among comatose patients. Active glucose transport across the blood-brain barrier into the central nervous system is impaired after severe brain injury, which may further compromise brain energetic function. Low levels of brain glucose associated with metabolic crisis despite normal CBF has been reported with blood glucose levels in the normal range

TABLE 34.4 Threshold Values in Brain Interstitial Tissue of Selected Biomarkers Associated With Worse Outcome

Biomarker	Threshold Values
Glucose (mmol/L)	<0.7 or >2.6
Lactate (mmol/L)	>4
Pyruvate (μmol/L)	<70
LPR	>40
Glutamate (mmol/L)	>20

Abbreviation: LPR, lactate-to-pyruvate ratio.

Clinical Use

A useful aspect of microdialysis monitoring is that derangements can precede impending deterioration, including elevated ICP in TBI patients or delayed neurologic injury in SAH patients. Severe derangements can be used to trigger emergent decompressive neurosurgical intervention, induction of hypothermia, or angiography to reverse ongoing ischemia. It is also potentially useful for helping to minimize the risk of critical brain tissue hypoglycemia when continuous insulin infusion is used to control stress hyperglycemia, to define the optimal individualized CPP thresholds, or to improve oxygen delivery either through ventilation strategies or blood transfusions.

CONTINUOUS ELECTROENCEPHALOGRAPHY

Technical advances and the era of digitization have made continuous electroencephalography (cEEG) monitoring an essential tool in neurocritical care. Specific uses include detection of seizures, titration of therapy for status epilepticus, monitoring for DCI in SAH patients, titration of sedation in refractory intracranial hypertension, and coma prognostication. Refer to Chapter 26 for a detailed discussion of basic electroencephalography (EEG) physiology and interpretation. Listed in the following sections are some of the recommended indications for EEG monitoring in the ICU setting (**Table 34.5**).

Seizure Detection

One of the main goals of cEEG is seizure detection. Ten percent to 30% of comatose patients have nonconvulsive seizures or nonconvulsive status epilepticus (NCSE) when monitored with cEEG depending on the primary diagnosis, and the vast majority are clinically undetectable (**Table 34.6**). Nonconvulsive seizures can directly produce depressed levels of consciousness and are associated with poor outcomes after all forms of severe acute brain injury.

TABLE 34.5 Indications for Continuous Electroencephalography in the Intensive Care Unit According to the Neurocritical Care Society and the European Society of Intensive Care Medicine

- All patients with ABI and unexplained and persistent altered consciousness
- All patients having suffered a seizure that are not back to their functional baseline 60 min after receiving AED
- During therapeutic hypothermia and within 24 h of rewarming in all comatose patients after cardiac arrest
- All comatose ICU patients without ABI but with unexplained impairment of mental status or unexplained neurologic deficits, particularly in those with severe sepsis or renal/hepatic failure
- In comatose SAH patients, in whom neurologic examination is unreliable, to detect DCI

Abbreviations: ABI, acute brain injury; AED, antiepileptic drug; DCI, delayed cerebral ischemia; ICU, intensive care unit; SAH, subarachnoid hemorrhage.

TABLE 34.6 Yield of Continuous Electroencephalography for Detecting Nonconvulsive Seizures or Status Epilepticus in Selected Conditions

Condition	Yield
Coma after termination of convulsive status epilepticus	48%
Lobar intracerebral hemorrhage	36%
Encephalitis or meningitis	36%
Cardiac arrest	22%
Traumatic brain injury	22%
Poor-grade SAH	18%
Septic encephalopathy	16%

Abbreviation: SAH, subarachnoid hemorrhage.

In TBI patients, nonconvulsive seizures are associated with elevated ICP, metabolic crisis, and long-term hippocampal atrophy.

Duration of monitoring is an important factor in the ability to detect seizures: A 30-minute spot EEG has approximately one-third the sensitivity of a 24-hour cEEG study. A minimum of 48 hours of cEEG monitoring is required to attain greater than 90% sensitivity for detecting nonconvulsive seizures or NCSE.

Surface cEEG in comatose patients often detects periodic or rhythmic patterns that appear to be highly epileptiform but fail to meet conventional diagnostic criteria for electrographic seizures. The term *ictal-interictal continuum* has been used to describe these patterns, which typically create vexing diagnostic and treatment dilemmas. Intracortical (or depth) EEG monitoring is an invasive form of focal electrical brain monitoring that can be used in addition to multimodality monitoring of CBF and $PbtO_2$ to determine whether these ictal-interictal patterns are truly ictal or not. Intracortical EEG has 2 to 3 times the sensitivity of surface EEG for detecting electrographic seizures in comatose patients.

Titration of Therapy for Status Epilepticus

cEEG is essential for guiding therapy for refractory status epilepticus (see Chapter 7). Delays in efficient treatment of status epilepticus lead to less therapeutic success and higher mortality. Almost 50% of patients presenting with convulsive status epilepticus who fail to recover consciousness after initial therapy continue to have evidence of nonconvulsive seizures or NCSE. Failure to urgently detect and treat these seizures leads to prolonged coma and increasing refractoriness to therapy. The EEG target of continuous infusion treatments for NCSE (ie, midazolam, propofol, ketamine, or pentobarbital) can range from simple elimination of ictal discharges to induction of burst suppression depending on the clinical scenario.

Monitoring for Delayed Cerebral Ischemia After Subarachnoid Hemorrhage

EEG is very sensitive to brain physiology, and changes in the EEG pattern are a promising way to detect DCI after SAH. Reduction in alpha variability and the alpha-to-delta ratio has been found to signal the imminent onset of DCI. Most interestingly, those changes can precede the onset of clinical symptoms by 1 to 2 days and might allow therapy titration with the surrogate objective of reversing the EEG anomaly.

Coma Outcome

Trends in the background EEG over several days of monitoring has prognostic value in coma. After cardiac arrest, improvement of the background from near isoelectric attenuation to burst suppression to a continuous pattern of diffuse slowing implies improving brain function and a more hopeful prognosis. Absence of a posterior dominant (ie, alpha) rhythm or reactivity of the background EEG to painful stimuli are poor prognostic signs; recovery of these findings implies a better chance of recovery. Comatose patients with electrographic seizures or generalized periodic epileptiform discharges have a worse prognosis than those with lateralized periodic epileptiform discharges, who in turn have a worse prognosis than those with no epileptiform activity. The presence of normal sleep architecture implies an extremely good likelihood of eventual recovery of consciousness.

Limitations of Continuous Electroencephalography

The main limitations of cEEG monitoring are technical and logistic. The recordings are subject to multiple artifacts from eye movement and other electrostatic forces. The continuous recordings constitute an incredible amount of data to be interpreted, and conclusions can vary from one reader to another. Automated systems are being developed, but raw cEEG remains a cost and labor-intensive modality requiring expert technical and medical staff. Advances in digital EEG now allow time-frequency analysis to be applied to raw signals to quantify EEG changes over time. It includes total EEG power; alpha, theta, or delta power; alpha power variability index; and alpha or theta/delta power ratios. For example, alpha/delta power ratio combines the decrease in fast activity and the increase in delta rhythm due to a CBF reduction. Tools such as color density spectral array might allow continuous, bedside, simpler visualization allowing nonexperts, including ICU nurses, to recognize significant events. Further research is still needed to validate practical approaches that can be applied to the general neuro-ICU population by nonneurophysiologists.

MULTIMODALITY MONITORING DATA ACQUISITION AND ANALYSIS

Since the advent of ICP monitoring, the number of monitored physiologic parameters in neurocritical care has grown faster than our ability to integrate it to a meaningful clinical management plan without special tools that allow us to store, review, and analyze the data. In addition to the brain-specific measurements discussed in this chapter, clinicians must take into account systemic physiologic variables such as heart rate, blood pressure, temperature, and end-tidal CO_2. The amount of data to integrate can be overwhelming.

The primary goal of ICU multimodality monitoring is to act as an alarm system to detect harmful physiologic processes before they lead to irreversible damage. A secondary goal is to allow neurointensivists to optimize the physiologic environment to prevent secondary injury from occurring altogether. In order to do so, modern ICUs will be increasingly grounded within an informatics infrastructure that allows for real-time synchronized data acquisition, storage, and analysis. Raw data must be processed to differentiate signals from noise and to eliminate artifacts.

Complex analysis systems are being developed to allow for automated event detection and to minimize unnecessary alarms. Information displays must be optimized to avoid information overload and assist in clinical decision making. All of this implies a greater role for informatics and artificial intelligence in neurocritical care units in the future. A stand-alone data acquisition system is commercially available at present (Moberg Research Inc, Ambler, PA), and two systems exist for data display and analysis (ICU Pilot, M Dialysis, Stockholm, Sweden; ICM+, University of Cambridge, Cambridge, United Kingdom).

Genetic Testing and DNA Diagnosis 35

Jill S. Goldman and Jacinda B. Sampson

KEY POINTS

1. A thorough family history is an essential first step for determining the likelihood of a neurogenetic disease, but a lack of family history does not rule out a genetic diagnosis.
2. Genetic counseling is an important part of testing, including anticipatory guidance.
3. Penetrance, phenotypic variability, and anticipation are important factors in both planning for and interpretation of genetic test results.
4. Testing strategies can vary by disease, available test modalities, and patient-centered factors.

INTRODUCTION

Enormous advances in genetic technology are changing what we know about the molecular mechanisms and causes of neurologic disease. As a result, genetic testing is becoming more common and, at the same time, more complicated. The need for both clinicians and patients to understand the various types of genetic tests and the implication of genetic results is greater than ever. This chapter reviews the process of genetic counseling, the genetic mechanisms that influence the appropriate choice of different types of genetic tests, and the interpretation of genetic results.

THE PROCESS OF GENETIC COUNSELING

Obtaining the Family History

A review of family history and drawing of a pedigree are the essential first steps for determining the likelihood of a neurogenetic disease. A carefully constructed pedigree can guide the differential diagnosis by indicating whether any family history exists and, if it does, the possible mode of inheritance. At least a three-generation family history should be obtained, which includes ethnicity, age of onset of symptoms, age and cause of death, diagnoses determined by genetic testing, and known history of consanguinity. Targeted family history questions can help to narrow the differential diagnosis. As an example, consider the patient with ataxia: A family history that includes mental retardation or premature ovarian failure would suggest a diagnosis of fragile X–associated tremor ataxia syndrome. Similarly, for a patient with amyotrophic lateral sclerosis and a family history of dementia, a likely cause is a hexanucleotide expansion in *C9orf72*. An Ashkenazi Jewish background in the presence of Parkinson disease could indicate an *LRRK2* or *GBA* mutation and, in the presence of dystonia, a *Tor1A* deletion (Table 35.1).

A lack of family history, however, does not rule out a genetic diagnosis. A negative family history may be due to lack of information, early death, autosomal recessive inheritance, undisclosed adoption, false paternity, or de novo mutations (mutations that first appeared in the patient).

The Genetic Counseling Discussion

The process of genetic counseling and testing differs, depending on whether the patient is being seen for diagnostic testing or for predictive testing. Regardless, enough time should be given to genetic counseling to provide the patient/family with the understanding of the implications of testing and the various types of test results. Clinicians may refer to the National Society of Genetic Counselors (http://www.nsgc.org) if they wish to locate a genetic counselor in their area. In general, patients should be encouraged to attend all counseling sessions with a support person who can help them interpret the information, support them through the process, and act as a contributor to the patient's history.

In the course of genetic counseling for diagnostic testing, the nature and genetics of the disorder, the implications of a positive result for other family members, the benefits, risks, and limitations of testing and an emotional impact of testing should always be discussed (**Table 35.2**).

Pretest counseling for predictive genetic testing is an opportunity for anticipatory guidance. Patients should be asked how they would feel both over the short term and long term upon receiving a positive or negative result. They should consider how a positive or negative result would impact their life decisions including relationships, school or work choices, financial decisions, and reproductive choices. Many patients may need referrals for psychological counseling to help them work through the decision to test. In fact, the Huntington disease genetic testing protocol, which is used by many centers for predictive testing for fatal, untreatable neurogenetic conditions, advocates for a psychiatric assessment of all patients prior to predictive testing (**Table 35.3**).

As with counseling for diagnostic genetic testing, the benefits, risks, and limitations of testing should be covered. In general, predictive testing should not be performed without confirmation of a genetic diagnosis (and known mutation) in another family member. Without a known mutation in the family, a negative result may falsely reassure the individual, or a discovery of a variant of unknown significance will be inconclusive without other informative cases in the family.

Whenever possible, genetic results should be given in person, especially when they are predictive. While delivering the results, the clinician should review the meaning of the test result for the patient and family members, assess the psychological state of the patient and refer for psychological counseling as necessary, determine a plan of action, and give information about appropriate disease associations and support groups. When a positive result has been given, the clinician should follow up with the patient/family following the posttest session.

TABLE 35.1 Family History Questions for Differential Diagnosis of Neurogenetic Disorders

Disorder	Specific Questions: "Has any family member ever had . . ."
Dementia	Dementia
	Memory problems or other cognitive problems
	Language or speech problems
	Personality or behavioral change
	Mental illness including depression
	Any other neurologic disease such as Parkinson disease, ALS
	Movement or gait disorder
	Strokes
	Migraines
	Seizures
Neuromuscular disease	Gait or walking problems
	Weakness
	Heart failure or pacemaker
	Developmental delay
	Learning disabilities
	Dementia or cognitive impairment
	Language or speech problems
	Personality or behavioral change
	Psychiatric illness including depression
	Vision problems, including early-onset cataracts
	Infertility
	Diabetes
Movement disorders	Dementia or cognitive impairment
	Learning disabilities or intellectual disability
	Language or speech problems
	Personality or behavioral change
	Mental illness including depression suicide
	Gait or walking problems
	Weakness
	Vision problems
	Infertility
	Tremor
	Seizures
	Writer's cramp or cramps in other muscles
Movement disorders *(continued)*	Abnormal posture
	Tics or other abnormal movements
	Alcoholism
	Clumsiness
	Immune deficiency
	Cancer
	Heart problems
	Hearing loss
Neuropathies	Walking problems
	Numbness, tingling, or pain in limbs
	Clumsiness
	Difficulty fitting shoes
Neurocutaneous disorders	Birthmarks or spots on skin
	Seizures
	Hearing problems
	Vision problems
	Tumors or growths that were removed
	Bumps on skin
	Scoliosis
	Intellectual disability or learning disabilities
	Heart problems, arrhythmias
	Kidney problems
	Stroke
	Cancer or tumors of brain, spinal cord, or peripheral nerve
Epilepsy	Seizures, infantile spasms
	Periods of staring or seeming vacant
	Headaches
	Vision problems
	Learning disabilities, autism, or autism spectrum disorders
Amyotrophic lateral sclerosis	Progressive weakness
	Speech or swallowing problems
	Gait or walking problems, wheelchair requirement
	Dementia

Abbreviation: ALS, amyotrophic lateral sclerosis.

GENETIC PHENOMENOLOGY

The genetics of neurologic disease is complicated by an array of genetic mechanisms. When considering a genetic etiology, all of these phenomena warrant attention and discussion with patients.

Incomplete and Age-Dependent Penetrance

Penetrance is the likelihood that an individual carrying a pathogenic mutation will develop the disorder caused by that gene. Incomplete penetrance can be found in many autosomal dominant conditions. Examples of incomplete penetrance include *DYT1* early-onset dystonia (about 30% of carriers develop symptoms) and *LRRK2*-related Parkinson disease (age-dependent penetrance increasing during the life span to less than 30%). Penetrance sometimes correlates with certain mutations within the gene but may also be influenced by other largely unknown genetic or environmental factors. In some disorders such as myoclonus-dystonia (ε-sarcoglycan or *SGCE*), the sex of the transmitting parent determines penetrance (most symptomatic individuals have inherited the mutation from their father).

TABLE 35.2 Genetic Counseling Discussion Points

Disorder symptoms and course
Genetics of the disease
• Gene/genes
• Modes of inheritance
• Penetrance
• Degree of variability in symptom expression
Implication of genetic testing for family members
• Recurrence risk for children
• Risk for siblings
• Carrier status of parents
Benefits of genetic testing
• Diagnosis
• Clinical trial candidacy
• Management, if applicable
• Ability to make reproductive choices, including preimplantation genetic diagnosis
• More information for life planning
• End of uncertainty
Risks of genetic testing
• Possible insurance discrimination (life, long-term care, and disability insurances), particularly for presymptomatic individuals

• Emotional impact
  ◦ For diagnostic testing—confirmation of risk to children
  ◦ For predictive testing—knowledge that one will (may) develop disorder

Limitations of genetic testing
• May not discover the genetic cause
• Variants of unknown significance
• For predictive testing: inability to predict age of onset, severity, or exact symptomology, incomplete penetrance (if applicable)
• The need to identify a mutation in an affected family member prior to predictive testing
Communication of test result
• Will the genetic result be shared with family or others? If so, how and when?
• Right of relative not to know—encourage family discussion before results are in.

Phenotypic Variability

Neurogenetic disorders can have remarkable inter- and intrafamilial variability in severity of symptoms, type of symptoms, age of onset, and disease course. Consider spinal muscular atrophy (SMA), which can occur in infancy and if untreated is a severe and rapidly fatal condition (SMA type 1) to onset in childhood (SMA type 2) to onset in adolescence or adulthood (SMA type 4) due to the influence of the modifier gene, *SMN2*. Hexanucleotide repeat expansions in the gene *C9orf72* can cause frontotemporal degeneration, amyotrophic lateral sclerosis, or both. Additional phenotypes that have been reported with this gene include ataxia, parkinsonism, Alzheimer-like dementia, and psychosis. *DYT1* can cause severe childhood dystonia with contractures, adult-onset writer's cramp, or no symptoms at all.

[a]From International Huntington Association, World Federation of Neurology Research Group on Huntington's Chorea. Guidelines for the molecular genetics predictive test in Huntington's disease. *Neurology*. 1994;44(8):1533-1536.

Some genotype/phenotype correlations exist, as with the D178N mutation in *PRNP*, which, when present on the same chromosome with the polymorphism codon 129M, causes fatal familial insomnia but, when with 129V, causes Creutzfeldt-Jakob disease. Another example is dystrophinopathy, where in-frame deletions are more likely to result in the milder Becker muscular dystrophy phenotype, and out-of-frame deletions result the more severe Duchenne muscular dystrophy phenotype, but there are frequent exceptions to the reading frame rule. At other times, unknown factors seem to influence gene expression.

Polynucleotide Repeat Expansion and Anticipation

Many examples of polynucleotide repeat disorders are found in neurogenetic disease. These include Huntington disease, many of the spinocerebellar ataxias, fragile X–associated tremor ataxia syndrome, and the myotonic dystrophies. Age of onset for these diseases is inversely correlated with the number of repeats; however, this correlation is insufficient to be used to predict the age of onset. Expansion of the allele size occurs during gamete formation so that the repeat number can increase, and therefore, age of onset can decrease with successive generations. This phenomenon is called *anticipation*. Contractions occasionally occur. Depending on the disorder, expansion is more common when being inherited from one parent over the other. For Huntington disease, spinocerebellar ataxias, and fragile X–associated tremor ataxia syndrome, expansion usually occurs in the father. In myotonic dystrophy type 1, large expansions more often occur in the mother and can result in a congenital form of the disease. Additionally, these conditions have ranges of repeats whereby the carrier is asymptomatic or will have a very late onset but can transmit an expansion to their children. Thus, a negative family history for these disorders is not uncommon.

Genetic Heterogeneity

Many neurogenetic diseases are multigenic. Presently, over 25 loci for dystonia and over 50 loci for hereditary spastic paraparesis have been reported. Testing for such conditions can be expensive and problematic. Although certain types of gene panels may be appropriate, the ordering clinician has to evaluate which genes are being tested and how. For some of the genes, such as *Parkin*, when sequencing does not reveal a mutation, duplication/deletion testing should be ordered.

Pleiotropy

Many genes causing neurologic conditions can cause problems in other systems as well. Examples of pleiotropy include hearing loss in fascioscapulohumeral muscular dystrophy and cataracts in myotonic dystrophy. For this reason, targeted questions about associated symptoms can help to clarify an otherwise negative family history.

Phenocopies

Neurologic conditions such as Alzheimer and Parkinson diseases represent some of the most common conditions in the population. Finding a genetic etiology for one of these diseases in one family member does not necessitate that another family member has the mutation, especially with an older onset.

TYPES OF GENETIC TESTS

Many options now exist for genetic testing of neurologic disease. Determining the most appropriate test is essential because they do not all analyze the same types of mutations. The ordering physician may want to consult with a geneticist, genetic counselor, or laboratory director before testing to ensure that they are ordering the correct test and that the test has clinical use. The cost of testing, and whether it will be covered by insurance, is another factor to consider. The types of genetic tests and their appropriate use are described in the following section.

Microarray

Microarray detects large deletions and duplications by detecting the relative signal of markers (single nucleotide polymorphisms) spaced through the genome; loss of a copy by a deletion results in a decreased signal; a duplication results in increased signal at that locus. Microarray does not detect single nucleotide point mutations or does it define the exact breakpoints of a deletion or duplication, only that it is present between the normal and changed copy number single nucleotide polymorphism. Microarray cannot pick up balanced translocations that can be seen on karyotypes but can pick up unbalanced ones. Insertions or deletions smaller than the spacing between microarray markers can be detected using a multiple ligation polymerase assay with polymerase chain reaction (PCR) primers designed to bind to an exon in question; if both primers can bind, they are ligated and amplified by PCR. If one primer is not able to bind its target sequence due to a deletion, no signal will be detected for the primer pair for that exon.

Testing for Polynucleotide Repeat Disorders

Small repeat sizes can be directly sequenced after PCR. Larger ones may require southern blot testing, where genomic DNA is cut with restriction enzymes around the repeat motif and separated on a gel. At larger sizes, polynucleotide repeat disorders may appear to be a smear rather than a single band—this reflects a range of repeat sizes called *somatic mosaicism*.

Sanger Sequencing

Primers are designed to bracket the sequence of interest, allowing PCR amplification followed by sequencing, an excellent way of detecting missense mutations or small deletions or duplications falling within the bracketing primers.

Next-Generation Sequencing (Next-Gen)

Genomic DNA is fragmented into small pieces, which are then sequenced and aligned by comparison to the reference human genome. This next generation sequencing technique (NextGen) is excellent at detecting point mutations and small insertions/deletions but may not detect larger insertions or deletions, cannot detect polynucleotide repeats, and can have difficulty aligning highly homologous sequences or detecting areas with high guanine-cytosine content. It can be used for designing panels of genes using a reagent to capture those sequences of interest. It can also be used for the whole exome sequencing (WES) or the whole genome sequencing (WGS).

A limitation of next-gen large panels and WES/WGS is that the more genes that are sequenced, the greater chance of discovering one or more variants of unknown significance (VUS). If a VUS is discovered, testing parents or other affected and unaffected relatives may be helpful establishing if the VUS is significant. A trio analysis of the patient and parents, or patient and 2 relatives, can be ordered for WES/WGS testing. Other VUS deleteriousness prediction tools used to interpret VUS significance include allelic frequency (is the variant present in population databases), effect of the VUS on amino acid sequence or splicing, and evolutionary conservation at that locus.

TESTING STRATEGY

More than one type of test may be available for a disorder, and more than one gene may cause a disorder. A panel may be useful by including other genetic disorders on the differential, avoiding serial testing. A single gene or panel may be less expensive, with a faster turnaround time, than exome or genome sequencing.

Pretest counseling is vitally important for genetic testing because most laboratories require informed consent. Patients and families should be counseled about the cost of testing, time until results, probability of finding a mutation, and limitations of a selected test. Counseling should also include information on whether insurance will cover the costs and their financial responsibility, whether the chosen test is the end of the diagnostic odyssey or if there may be more testing in their future and how a confirmation of genetic diagnosis may affect their prognosis, their medical care, and their family. It is important to allow sufficient time for these discussions and questions.

Acute Ischemic Stroke 36

Charles C. Esenwa and Stephan A. Mayer

KEY POINTS

1. Acute ischemic stroke is defined by critical loss of blood flow with resultant cerebral, spinal cord, or retinal infarction within a specific vascular territory.
2. Core infarct is surrounded by an area of potentially salvageable tissue, called the *penumbra*, in which cerebral blood flow is sufficient to temporarily support cell survival but insufficient to maintain normal function.
3. Intravenous thrombolysis as far out as 4.5 hours after symptom onset or last known well time is standard first-line therapy for all eligible patients.
4. Mechanical thrombectomy using retrievable stent devices decreases long-term disability in all patients with large-vessel occlusion presenting within 6 hours.
5. Thrombectomy can also benefit large-vessel occlusion patients 6 to 24 hours from last known well if a substantial amount of salvageable penumbral tissue is identified on computed tomography perfusion imaging.
6. Standardized management in a dedicated stroke or neurointensive care unit reduces stroke-related morbidity and mortality.
7. Decompressive hemicraniectomy is a powerful life-saving intervention for patients with completed middle cerebral artery or cerebellar infarction.

INTRODUCTION

Ischemic stroke is defined as an episode of neurologic dysfunction caused by vascular stenosis, spasm, or occlusion leading to focal cerebral, spinal cord, or retinal infarction within a specific vascular territory. With the development of acute reperfusion therapies, streamlined algorithms for management of acute ischemic stroke (AIS) are necessary for effective treatment. Management revolves around the processes of (1) early diagnosis, including early stroke recognition and notification of emergency medical services (EMS); (2) rapid clinical and radiologic assessment; (3) early administration of intravenous (IV) thrombolytic therapy; (4) performing advanced catheter-based mechanical thrombectomy in appropriate patients with large-vessel occlusion (LVO); and (5) specialized poststroke management in either a stroke unit or neurologic intensive care unit (ICU).

Epidemiology

An estimated 650,000 AIS occur each year in the United States alone. The most significant individual risk factors for ischemic stroke include hypertension, diabetes mellitus, cigarette smoking, poor nutrition, physical inactivity, cardiac dysrhythmia, alcohol consumption, and obesity. Other causes of AIS include paradoxical embolism through a parent foramen ovale (PFO), cervical dissection, inflammatory or infectious vasculitis, genetic or congenital vasculopathy (eg, carotid web), and systemic hypercoagulable states. In-hospital mortality after AIS is relatively rare, occurring in approximately 5% of cases, and is associated with increasing age, stroke severity, history of atrial fibrillation, previous stroke, carotid stenosis, diabetes mellitus, and history of coronary artery disease. Functional disability and morbidity from poststroke complications occur much more commonly, affecting the majority of patients. As a result, only half of AIS patients are discharged home, whereas the remainder requires further care in skilled nursing facilities, rehabilitation, or palliative care centers.

Pathobiology

Despite making up only 2% of total body weight, the brain consumes 20% of the body's total energy and relies on a constant supply of glucose and oxygen to maintain function and structural integrity. Each minute, nearly 1 L of blood is supplied to the brain through the carotid arteries and, to a lesser extent, the vertebrobasilar system. To ensure a constant cerebral blood flow (CBF) across a range of blood pressures and metabolic states, cerebral vessels constrict or dilate in response to changes in the concentration of carbon dioxide, oxygen, and vessel wall shear stress related to velocity of blood flow. The primary mediator of vasodilation is nitric oxide, which acts to relax the circumferential smooth muscle cells in the tunica media. In normal brain, researchers have described a feed-forward mechanism in which neurovascular coupling is achieved through neuronal innervation of astrocytes, pericytes, and endothelial cells. In this scenario, neurons respond to increased metabolic activity by directly modulating local arteriolar and capillary vasoactivity. It has been shown that endothelial and smooth muscle cells then propagate vasodilation along the neighboring vascular matrix through spreading hyperpolarization and a resultant myogenic response.

CEREBRAL BLOOD FLOW REDUCTION

When cerebral perfusion pressure falls below approximately 60 mm Hg due to either systemic hypotension or local arterial blockage, autoregulatory vasodilation cannot compensate leading

FIGURE 36.1 Cerebral autoregulation. With autoregulation intact (*red line*), cerebral blood flow (CBF) begins to fall below a normal range of 60 mL/100 g/min and hits a critical ischemic level of approximately 20 mL/100 g/min. When autoregulation is impaired or absent (*green line*), CBF can fall to critical levels when mean arterial pressure (MAP) is as high as 50 mm Hg.

to decreased CBF from its normal range of 50 to 60 mL/100 g/min (Fig 36.1). When CBF falls below 30 mL/100 g/min, regional exchange of nutrients and oxygen fails within the neurovascular unit (endothelial cell, surrounding pericytes, basement membrane, perivascular astrocytes, and adjoining neurons), resulting in pathologic depolarization of neurons and glia and suppression of the normal electrical activity as evidenced by slowing and attenuation of the electroencephalographic background (Fig 36.2). Sustained severe hypoperfusion, with CBF levels falling below 20 mL/100 g/min, triggers a cascade of ischemic injury that can lead to irreversible neuronal necrosis and cerebral infarction.

FIGURE 36.2 Progression of ischemic tissue to infarction over time as a function of cerebral blood flow (CBF). A CBF level below 20 mL/100 g/min is the level below which tissue progresses through a phase of reversible ischemic injury to infarction. Lower CBF produces more intense ischemia and faster progression to infarction.

Infarct Core and Penumbra

With decreases in CBF below 20 mL/100 g/min, assuming a normal rate of neuronal metabolism, brain tissue progresses from a state of reversible electrical dysfunction to a "penumbral" state of excitotoxic damage and programmed cell death (apoptosis). *Penumbra* is an ancient Latin term that refers to the shadow that advances across the land in advance of the complete darkness of a solar eclipse. In modern stroke therapy, penumbral tissue is brain tissue in the shadow of death.

Failure of the sodium/potassium transmembrane adenosine triphosphate pump occurs first, causing neurons and glia to depolarize. Widespread depolarization causes uncontrolled release of excitatory neurotransmitters such as glutamate, which in turn leads to an intracellular influx of calcium and sodium. Once the phase of excitotoxicity and apoptosis has set in, a phase of bioenergetic failure occurs with ionic pump dysfunction and loss of normal transmembrane sodium and calcium gradients.

In the infarct core, where the bioenergetic failure is greatest, these massive electrolyte shifts cause water to passively follow its osmotic gradient resulting in cellular swelling and eventual lysis. The resultant edema, termed *cytotoxic edema* as it results from intracellular swelling, manifests within minutes of the initial insult and can be detected with magnetic resonance imaging (MRI) as hyperintensity on diffusion-weighted imaging (DWI) sequences.

The core of the infarct is surrounded by an area of relative hypoperfusion, the ischemic penumbra, in which CBF is sufficient to temporarily support cell survival but insufficient to maintain normal cellular function indefinitely (Fig 36.3). Penumbral tissue may be salvageable if adequate perfusion to the territory can be restored in a timely fashion, which is the basis for all AIS reperfusion therapies. Penumbral tissue, however, is inherently unstable and commonly will progress to completed infarction over time, making *time to reperfusion* the most important therapeutic factor for improving neurologic outcome and preventing disability and mortality after AIS.

Completed Infarction

It is estimated from human and experimental studies that the time from vessel occlusion to fully completed infarction in most cases ranges from 3 to 6 hours. Once the tissue becomes necrotic and infarcted, it is easily visible on both computed tomography (CT) and fluid-attenuated inversion recovery MRI scans. The CBF is maintained at near-normal levels up to the margin of a completed infarct where it rapidly drops to undetectable levels as long as the affected vessel remains occluded. Over the next several days, the infarct progressively swells. Ischemic cells that progress to frank infarction release various proinflammatory cytokines and proteases that disrupt the architecture and function of the neurovascular unit, increasing permeability of the blood-brain barrier. Apoptosis is triggered through the function of various inflammatory processes, including the receptor/ligand combination of the CD95 receptor and tumor necrosis factor–related apoptosis-inducing ligand and mitochondrial membrane release of cytochrome *c* oxidase, both of which lead to activation of the intrinsic programmed cell death cascade and delayed cell death. This delayed neurologic injury could in theory be prevented with neuroprotective agents, although none has proven to be of use in clinical trials.

FIGURE 36.3 Dynamics of infarct core and penumbra topography over time in focal ischemia. In the earliest minutes to hours, only a portion of the total brain territory at risk is ischemic as a small core of infarct begins to form. Between 2 and 4 hours, the penumbra moves peripherally in a dynamic fashion around a progressively infarct core and collateral failure may lower CBF in some of the outermost regions of the territory at risk to ischemic levels. Beyond 4 hours, the penumbra evolves into a relatively thin rim of ischemic tissue around a large core of infarcted tissue making reperfusion less effective, as amount of salvageable tissue dwindles and the risk of hemorrhagic infarction increases.

The parenchymal inflammatory response results from upregulation of endothelial cell leukocyte adhesion receptors that cause leukocyte adhesion and transmigration into the affected tissue and is responsible for the prolonged process of tissue inflammation and remodeling after an infarct is completed, as the swelling resolves and the involved regions convert to gliotic scar tissue.

ETIOLOGY OF ISCHEMIC STROKE

The microscopic process of acute cerebral infarction is preceded by macrovascular occlusion of the territory in question. Accurate classification of AIS etiology is important to understand poststroke prognosis, quantify the risk of recurrence, and guide strategies for secondary stroke prevention. Although imperfect, the Trial of Organon in Acute Stroke Treatment classification criteria is the most widely accepted ischemic stroke classification system and includes the following five subtypes: large artery atherosclerosis (15%-40%), cardioembolic (15%-30%), small-vessel occlusion or "lacunar" (15%-30%), cryptogenic (up to 40%), and "other" cause (<5%) (Fig. 36.4).

Large Artery Atherosclerosis

Atherosclerotic plaque may develop at any point along the extracranial or intracranial arterial tree but is usually seen at vessel-branch points where turbulent flow occurs, most commonly at the common carotid bifurcation, vertebral artery origin, vertebrobasilar junction, or the origin of the middle or anterior cerebral arteries. Atherosclerotic plaque causes ischemic stroke by one of two mechanisms: hypoperfusion across a region of critical stenosis or, more commonly, plaque rupture leading to thrombus formation and subsequent distal embolization of thrombus or plaque fragments.

Artery-to-artery embolism occurs when fragments of atherosclerotic plaque or fresh thrombus formed on top of the plaque embolize to occlude a distal vessel. Plaques with a lipid-rich necrotic core and thin fibrous cap pose a risk of spontaneous rupture and activation of the coagulation cascade leading to superimposed thrombus formation. Biomechanical forces induced by turbulent blood flow along this irregular portion of vessel can act to destabilize the cholesterol plaque or dislodge a superimposed thrombus. When this happens, the thrombus may rapidly dissolve causing the clinical symptoms to be fleeting or absent, or it may persistently occlude a distal vessel leading to lasting symptoms of AIS.

Clinically, ischemia from large-artery atherosclerosis is difficult to distinguish from stroke originating from the heart (cardioembolic stroke). Favoring the former are repeated transient ischemic attacks or completed infarcts within the same vascular territory, the best example of which is repeated episodes of painless *transient monocular blindness* related to ipsilateral carotid artery atherosclerosis. This condition, known as *amaurosis fugax*,

FIGURE 36.4 Stroke subtypes. This figure shows the Trial of Org 10172 in Acute Stroke Treatment classification criteria for ischemic stroke and the estimated relative distribution of stroke within each category.

results from cholesterol embolism from the carotid plaque causing occlusion of the central retinal artery or one of its branches. When the lumen of the carotid artery is nearly occluded, transient attacks can also be due to retinal hypoperfusion, clinically manifesting as vision loss with exposure to bright light. Similarly, repeated episodes of vertigo, diplopia, hemiparesis, hemianesthesia, gait unsteadiness, and even loss of consciousness can be a sign of high-grade vertebral or basilar artery stenosis.

Cardioembolic Stroke

Cardioembolic stroke includes all strokes caused by a cardiac source of thromboembolism. Most commonly, cardioembolism occurs from thrombus formed in the left atrial appendage of the heart in patients with atrial fibrillation, but cardioembolism can also result from a diseased native or prosthetic heart valve or ventricular wall thrombus resulting from recent myocardial infarction or severe dilated cardiomyopathy. Cardioembolic strokes can also result from neoplastic causes, such as atrial myxoma or marantic endocarditis, or infectious causes such as infectious endocarditis. Radiologically, scattered strokes at the gray-white matter junction that occur in both hemispheres, or in both the anterior and posterior circulation, are most commonly cardioembolic in origin. However, strokes that appear in association with proximal LVOs or that appear most consistent with small-vessel infarction can also be seen after cardioembolism.

Small-Vessel Infarction

Lacunar strokes from small-vessel occlusion are clinically defined by five general subtypes: (1) pure motor hemiparesis, (2) pure sensory syndrome, (3) mixed sensorimotor syndrome, (4) ataxic hemiparesis, and (5) clumsy-hand dysarthria, although various other manifestations can occur depending on the territory of the vessel involved. These strokes result from blockage of small perforating arteries arising from the middle cerebral artery (MCA) (lenticulostriate), the posterior cerebral or posterior communicating arteries (tuberothalamic, paramedian, posterior choroidal, inferolateral), and basilar artery (pontine perforators). These vessels are prone to segmental arterial wall disorganization and fibrosis, a process known as *lipohyalinosis*, and microatheroma formation. Over time, the arterial wall thickens and the vessel lumen is compromised causing a region of acute ischemia that is usually smaller than 1.5 cm in diameter. Hypertension is the greatest risk factor, although diabetes, age, and smoking may contribute as well. Lacunar infarction occurs most commonly in the basal ganglia, thalamus, internal capsule, corona radiata, and pons. Imaging helps distinguish lacunar stroke from other types of stroke by their subcortical location and relatively small size.

Undetermined Cause of Stroke

The etiology of up to 40% of strokes remains *cryptogenic*, or undetermined, even after extensive laboratory and radiologic investigation. The majority of cryptogenic strokes are territorial and appear to be embolic, despite the absence of atrial fibrillation, carotid or proximal large vessel disease, intracardiac thrombus, or other causes, in which case the term *embolic stroke of unknown source* is frequently used. Many embolic stroke of unknown source patients in fact have undiagnosed paroxysmal atrial fibrillation with studies showing that 10% to 20% of "cryptogenic" stroke patients are found to have occult atrial fibrillation on prolonged ambulatory cardiac monitoring. Although PFO and atrial septal defect are also associated with cryptogenic stroke, PFO closure should only be considered in patients younger than age 60 years with presumed paradoxical embolism and in whom no other identifiable stroke etiology could be established. The presence of an atrial septal aneurysm or large interatrial shunt makes it more likely that the cause of stroke is PFO related. Five large randomized controlled trials have evaluated the efficacy of PFO closure comparing it to medical therapy alone, in the setting of cryptogenic stroke. A meta-analysis including 3,440 patients found PFO closure to be associated with a 0.96% absolute reduction in recurrent stroke (1.04% vs 2.00% per 100 patient-years), compared to medical therapy alone. This relatively minor but statistically significant benefit of stroke reduction is partly offset by the risk of atrial fibrillation with PFO closure, which occurred between 1.8% and 6.6%, depending on the closure device and trial in question LEVEL 1.[1]

Other Causes of Stroke

The "other" causes of stroke category makes up less than 5% of AIS, and it is defined by a specific disease process that is shown to have a temporal relationship or association to the stroke. In addition, diagnostic investigation should not reveal any other more common mechanism. Examples include stroke due to hematologic disorders (eg, hypercoagulability, sickle cell anemia), infectious or inflammatory disease, intrinsic disease of the arterial wall (ie, vasculopathy), vessel dissection, genetic disorders, or iatrogenic causes. Coronavirus disease 2019 can cause a chronic inflammatory and hypercoagulable state and has been associated with large vessel embolic stroke in 0.5% to 1% of cases.

CLINICAL MANIFESTATIONS

Ischemic strokes can be defined clinically by the nature of the associated neurologic deficit with signs and symptoms fitting into defined syndromes representing specific vascular territories (Fig. 36.5). Knowledge of the following major stroke syndromes

FIGURE 36.5 Cerebral vascular supply. ICA, internal carotid artery; PCA, posterior cerebral artery.

TABLE 36.1 Syndromes of Cerebral Infarction

Arterial Distribution	Subdivision	Syndrome
Middle cerebral	Main trunk	Variable combination of hemiplegia, hemianesthesia, gaze deviation/preference, hemianopia and global aphasia (dominant hemisphere), or profound multimodal hemineglect (nondominant hemisphere)
	Upper division	Variable combination of hemiparesis, hemianesthesia, gaze deviation, and expressive (Broca) aphasia (dominant hemisphere) or hemineglect (nondominant)
	Lower division	Variable combination of hemianopia or quadrantanopia, mild or absent hemiparesis, receptive (Wernicke) aphasia (dominant hemisphere), or hemineglect and behavior disorder (nondominant)
	Perforating branches	Contralateral hemiparesis occasionally seen in combination with ataxia or dysarthria
Internal carotid		Can be asymptomatic or cause any of the following: ipsilateral monocular blindness, transient limb shaking, or a combination of middle cerebral and anterior cerebral artery syndromes
Anterior cerebral		Variable combination of hemiparesis and sensory loss of the contralateral leg more than the arm, transcortical motor aphasia (dominant hemisphere), motor neglect (nondominant hemisphere), impaired responsiveness ("abulia"), gait apraxia, ideomotor apraxia, or tactile anomia (nondominant hemisphere)
Posterior cerebral	Main trunk	Variable combination of hemianopia or quadrantanopia, alexia, color anomia, inability to perceive parts of an objects as a whole ("simultanagnosia"), face blindness ("prosopagnosia"), amnesia, agitated delirium (especially when bilateral), or cerebral blindness (with bilateral injury)
	Perforating branches	*Thalamus*: pure sensory stroke that may leave a residual pain syndrome ("thalamic pain syndrome"), ataxia, aphasia (dominant), hemineglect (nondominant), visual field deficits, memory loss, or behavioral disturbances *Subthalamic nucleus*: hemiballism *Midbrain*: various eye movement abnormalities, depressed level of arousal, hemianesthesia, hemiparesis, hemiataxia, hemiparkinsonism

can oftentimes accurately predict the territory of infarction and specific vessel involved (Table 36.1). Exceptions arise when there is underlying preexisting central nervous system injury, presence of collateral circulation, or variations in the vascular or brain anatomy that can produce atypical or unexpected clinical presentations.

Middle Cerebral Artery Infarction

Infarction of the MCA produces clinical syndromes that depend on the extent of the infarct and the side and level of vessel occlusion. Proximal, or branch MCA occlusion, can affect both the deep and the cortical hemispheric structures or deep structures only when there is robust collateral vascularization supplying the cortex. Isolated ischemia of the deep cerebral structures—mainly the internal capsule, basal ganglia, and corona radiata—occurs due to blockage of the lenticulostriate artery origins causing contralateral hemiparesis and possibly hemisensory loss that often is indistinguishable from a lacunar syndrome. Larger deep infarcts ("striatocapsular infarction") that affect cortical connections to the thalamus and optic radiations can cause the cortical syndromes of hemineglect, aphasia, and homonymous hemianopia or quadrantanopia.

Cortical ischemia in the MCA territory is encountered in isolation when vessel occlusion is localized to the superior or inferior MCA divisions (the number and location of these branch arteries can vary). Damage to either hemispheric cortex can cause contralateral limb weakness, contralateral sensory loss, astereognosia (inability to identify objects using touch), agraphesthesia (inability to recognize writing traced on the skin), diminished two-point discrimination, contralateral visual field deficits, and gaze deviation toward the damaged side. Ideational apraxia (inability to understand the purpose of an object or manipulate it) follows left-sided or bilateral hemispheric damage.

Syndromes resulting from a dominant (usually left) hemispheric lesion include aphasia (language dysfunction), bilateral ideomotor apraxia (inability to perform learned motor tasks), and buccolingual apraxia (inability to voluntarily direct mouth and tongue movements). The type and severity of aphasia depends on the location and size of the infarct. A superior MCA branch occlusion will affect the anterior perisylvian cortex and specifically the inferior frontal gyrus to produce Broca (expressive) aphasia that is characterized by decreased or absent word fluency and inability to write but with preserved comprehension. When aphasia is expressive or global, hemiparesis is also usually present and severe. Inferior branch MCA occlusion, affecting the posterior perisylvian cortex and specifically the superior temporal gyrus and temporoparietal junction, produces Wernicke (receptive) aphasia, which is characterized by preserved fluency and prosody but incomprehensible content; semantic and phonemic paraphasic errors; impaired comprehension; and inability to read, name, or repeat. Receptive aphasia is often associated with a homonymous hemianopia or quadrantanopia, but hemiparesis can be mild or even absent. Gerstmann syndrome (left-right confusion, finger agnosia, acalculia, and agraphia), or an incomplete version of this tetrad, follows infarction of the dominant angular gyrus.

Infarction of the nondominant (usually right) parietal lobe produces contralateral hemispatial neglect or an inattention to sensory inputs or motor outputs to the contralateral half of the environment or body. Specific findings include sensory or visual neglect (that can involve the entire contralateral visual field or be specific to various objects), anosognosia (lack of awareness of neurologic deficits), asomatognosia (inability to recognize one's limb on the affected side), and allochiria (spatial transposition

resulting in the patient attending to the ipsilateral hemispace when presented with a stimulus on the neglected contralateral side). Constructional apraxia (inability to assemble or draw objects) may result from damage to either hemisphere but is more obvious in nondominant hemispheric lesions. Although speech content or the propositional aspect of speech is preserved, a nondominant hemispheric lesion may cause deficits in the pragmatics, or sociolinguistic aspects of speech, involving tone and inferred intent.

Anterior Cerebral Artery Infarction

Anterior cerebral artery (ACA) infarction most commonly causes contralateral leg hemiparesis and/or hemisensory loss, although many other features may also be seen. Similar to watershed infarcts, ACA territory infarcts can cause transcortical aphasia of the motor type. *Motor neglect*, or a disinclination to use the contralateral limb despite the absence of weakness, is often encountered and is due to dysfunction of the prefrontal supplementary motor cortex. Bilateral ACA infarction often results in executive dysfunction with motor inertia and *abulia* (paucity of spontaneous behaviors) or even *akinetic mutism* (awake unresponsiveness). *Gait apraxia*, although typical of bilateral lesions, can also result from unilateral strokes. *Alien hand syndrome* (unwilled motor activity) or hemiballism of the contralateral arm can result from injury to the anterior corpus callosum or medial frontal cortex. *Utilization* and *imitation behavior* are neurobehavioral syndromes that can occur with unilateral prefrontal infarcts. With utilization behavior, the patient automatically and impulsively grabs objects that appear within visual field and are within reach. Imitation behavior is automatic and involuntary imitation of the examiner's movements.

Occlusion of the recurrent artery of Heubner, a large perforating artery arising from the proximal ACA, leads to infarction of the head of the caudate, anterior internal capsule, and anterior putamen. Common clinical features include dysarthria, motor perseveration, contralateral hemiparesis, abulia, and incontinence.

Internal Carotid Artery Infarction

Acute carotid occlusion causes acute hemispheric hypoperfusion that, in the absence of a patent circle of Willis, can manifest as seizure, contralateral limb shaking, or holohemispheric infarction of both the ACA and MCA territories. Occasionally, and especially in the presence of a robust circle of Willis, occlusion of the internal carotid artery (ICA) spares the ACA and produces a clinical scenario indistinguishable from branch MCA infarction. If collateral flow across the posterior communicating artery, anterior communicating artery, or pial arteries is adequate, the occlusion can be clinically silent or only affect smaller susceptible areas. By contrast, ICA occlusion with poor collateral or a distal ICA "T occlusion" can lead to catastrophic holohemispheric infarction with sparing of only the posterior cerebral artery (PCA) territory (thalamus and medial temporal and occipital lobes).

Border Zone Infarction

Border zone (or watershed) territories occur at the boundaries between the anterior, middle, and posterior cerebral arteries and are susceptible to ischemia in severe carotid artery stenosis or occlusion, or global hypoperfusion. *Superficial border zone infarction* occurs high along the convexity of the corona radiata between the deep and cortical structures anteriorly between the ACA and MCA territories or posteriorly between the MCA and PCA territories (**Fig. 36.6**). This pattern of infarction occurs when collateral flow is able to supply the majority of the involved territories but is unable to "meet" between territories. Resulting symptoms form a combination of weakness, hemisensory loss, and cortical signs. Transcortical aphasia of the expressive or receptive type with relatively preserved ability to repeat is also common. The ACA-MCA watershed infarcts primarily cause arm weakness because the affected region corresponds anatomically with neurons in the motor strip that innervate the upper extremities. When bilateral, as occurs with cardiac arrest, ACA-MCA watershed infarctions result in *man-in-the-barrel syndrome* characterized by proximal bilateral arm and leg weakness with relative preservation of facial and distal extremity strength.

FIGURE 36.6 Schematic representation of different topographic patterns of cerebral infarction. (*A*) Territorial infarction (from posterior cerebral artery occlusion). (*B*) Watershed border-zone infarction (between the territories of the anterior cerebral artery and the middle cerebral artery). (*C*) Internal border zone infarction (deep middle cerebral artery territory). (*D*) Lacunar infarction (lenticulostriate-penetrating artery occlusion). (Adapted from Marshall R, Mayer S. *On Call Neurology*. 3rd ed. Philadelphia: Saunders; 2007.)

Internal border zone infarction (see **Fig. 36.6**) can occur with total ICA occlusion or with large MCA branch occlusions. Noncollateralized deep-penetrating arteries that descend from the cortex to the lateral wall of the ventricles represent the most hemodynamically vulnerable "distal field" in this scenario. The result is a pattern of multiple small deep infarcts involving the deep white matter of the corona radiata and centrum semiovale.

Anterior Choroidal Artery Infarction

The anterior choroidal artery is the last branch of the ICA originating just proximal to the ACA-MCA bifurcation. It traverses posteriorly to supply a number of structures, including the internal capsule, lateral thalamus, and the lateral geniculate body or optic radiations. Thus, occlusion of the anterior choroidal

artery results in the classic syndrome of contralateral hemiparesis, hemianesthesia, and homonymous hemianopia. Occasionally, cortical symptoms such as aphasia or hemineglect can result from disruption of thalamocortical white matter tracts.

Posterior Cerebral Artery

Occlusion of the PCA will cause infarction of the occipital and inferior temporal lobes. The usual presentation is sudden onset of a contralateral homonymous hemianopia. Bilateral occipital lobe lesions can cause *Anton syndrome* (cortical blindness unrecognized by the patient). *Charles Bonnet syndrome*, or release visual hallucinations, can also be seen in cortical blindness from bilateral occipital lobe injury. *Balint syndrome* is seen in bilateral parietooccipital junction infarcts and is characterized by simultanagnosia (inability to perceive parts of an object as a whole), oculomotor apraxia (incoordination of gaze), and optic ataxia (poor hand coordination using visual guidance). Hemineglect, although uncommon with occipital lesions, can be seen when the injury extends to the parietal lobe. Left PCA infarcts that involve either the deep white matter of the temporoparietal junction or the splenium of the corpus callosum may cause alexia without agraphia, a type of disconnection syndrome between the nondominant occipital cortex and the language-processing area in the dominant parietotemporal cortex. Inferomedial temporal lobe infarction may cause agitated delirium or global amnesia.

Proximal PCA infarction affecting the thalamic perforating arteries will lead to infarction of the thalamus or midbrain. If the ventral posterior nucleus of the thalamus is preferentially affected, the patient will have contralateral hemianesthesia. Hyperpathia may subsequently develop in a condition called the *Dejerine-Roussy* or *thalamic pain syndrome*. As the thalamus serves as a relay to the cortex, thalamic infarction can also cause a variety of atypical symptoms such as ataxia, aphasia (dominant), hemineglect (nondominant), visual field deficits, memory loss, or behavioral disturbances.

Lethargy or coma can result if the reticular activating system in the midbrain or thalami is affected and will often be accompanied by oculomotor abnormalities. Alterations in consciousness are especially common in the presence of an anatomically variant artery, termed the *artery of Percheron*, which supplies the bilateral medial thalami and rostral midbrain from a single vessel originating from a unilateral PCA. Midbrain lesions, when posterior, cause Parinaud syndrome characterized by sustained conjugate downgaze, upgaze paralysis, convergence-retraction nystagmus, lid retraction or Collier sign, and pupillary light-near dissociation.

Vertebrobasilar Territory Infarction

The basilar artery is the main conduit to supply the PCA arteries, and basilar thrombosis can manifest with a combination of medullary, pontine, midbrain, and posterior cortical signs. Basilar thrombosis leading to infarction of the anterior pons bilaterally causes "locked-in" syndrome: complete bilateral face, arm, and leg paralysis with isolated preservation of vertical eye movements and preservation of consciousness. Infarcts resulting from small-vessel thrombosis of the pontine-perforating arteries cause a combination of cranial nerve dysfunction, long tract signs, reflexive posturing or hyperreflexia, sensory loss, and/or cerebellar findings. Small anterior pontine strokes can also produce lacunar syndromes without cranial nerve deficits that are clinically indistinguishable from anterior circulation lacunes. Oculomotor or gaze palsies, including internuclear ophthalmoplegia and skew deviation, or nystagmus, are also common. *Top of the basilar* syndrome refers to occlusion of bilateral distal basilar and proximal PCA thalamic- and midbrain-penetrating arteries from embolism. The result is a pattern of bilateral small-vessel infarcts involving the midbrain and thalami with asymmetric ophthalmoparesis, horizontal and vertical gaze abnormalities, skew deviation, changes in level of consciousness, and variable bilateral motor and sensory deficits.

Infarction of the lateral medulla occurs when the posterior inferior cerebellar artery or a branch of the vertebral artery is affected. What results is a lateral medullary or *Wallenberg syndrome*, which is characterized by vertigo, ipsilateral ataxia, loss of pain and temperature sense in the ipsilateral face and the contralateral arm and leg, dysphagia, and ipsilateral oculosympathetic syndrome (*Horner syndrome*). Other brainstem infarct syndromes are described in **Table 36.2**.

DIAGNOSIS

Symptom Recognition

Delay in prehospital recognition of stroke symptoms is the greatest barrier to prompt treatment and a major factor in explaining why less than 10% of patients with AIS receive fibrinolytic therapy. Despite the established benefit of timely assessment and the potential for neurologic recovery with early treatment, only approximately 20% of patients present within 2 hours of symptom onset and approximately 25% within the therapeutic window of 4.5 hours. Limited insight and lack of community-level awareness to the time-sensitive nature of treatment are partly to blame, with studies suggesting that only 5% of people in an urban population have knowledge of at least three stroke symptoms. The mnemonic FAST (face, arm, speech, time to call 911) has been disseminated using multiple community education efforts, in order to raise awareness about stroke symptoms and the urgent nature of seeking medical care. Public education efforts play a critical role in increasing the proportion of patients who present within the therapeutic time window.

Once EMS is activated, first responders must quickly and accurately characterize the symptoms of a stroke. Prehospital stroke scales (**Table 36.3**) should be used to assist in the screening and rapid triage process LEVEL 2.[2] The most widely used are the Cincinnati Prehospital Stroke Scale; the Los Angeles Motor Scale; the Face, Arm, Speech Test; and the Rapid Arterial oCclusion Evaluation scales. All allow for the rapid identification of hemiparesis, speech disturbances, and other signs of focal neurologic deficit and can be performed in a matter of minutes. With the advent of mechanical thrombectomy for treating qualifying patients with LVO, early screening and identification of patients with LVO is an integral part of any regional stroke systems of care protocol. Similar to ST-elevation myocardial infarction pathways, a positive LVO screen allows for high-likelihood patients be rerouted to thrombectomy-capable centers by EMS or be transferred emergently from one hospital to another capable of providing advanced reperfusion therapies. In many instances, regional stroke systems are dependent on real-time image sharing and 24/7 remote audiovisual communication capabilities provided by a trained neurologist LEVEL 2.[2] A study by McTaggart

TABLE 36.2 Syndromes of Brainstem Infarction[a]

Syndrome		Artery Affected	Structure Involved	Manifestations
Medial syndromes	Medulla	Paramedian branches of basilar artery	Emerging fibers of 12th nerve	Ipsilateral paralysis of tongue
			Corticospinal tract	Contralateral limb paresis/paralysis
			Medial lemniscus	Contralateral hemianesthesia
	Inferior pons	Paramedian branches of basilar artery	Pontine gaze center, near or in nucleus of sixth nerve	Paralysis of gaze to side of lesion
			Emerging fibers of sixth nerve	Ipsilateral abduction paralysis
			Corticospinal tract	Contralateral limb paresis/paralysis
	Superior pons	Paramedian branches of basilar artery	Medial longitudinal fasciculus	Internuclear ophthalmoplegia
Lateral syndromes	Medulla	Posterior inferior cerebellar artery or vertebral artery branches	Emerging fibers of 9th and 10th nerves	Dysphagia, hoarseness, ipsilateral paralysis of vocal cord; ipsilateral loss of pharyngeal reflex
			Vestibular nuclei	Vertigo, nystagmus
			Descending tract and nucleus of fifth nerve	Ipsilateral facial analgesia
			Solitary nucleus and tract	Taste loss on ipsilateral half of tongue posteriorly
			Spinothalamic tract	Contralateral sensory loss
			Hypothalamospinal tract	Ipsilateral oculosympathetic dysfunction ("Horner syndrome")
	Inferior pons	Anterior inferior cerebellar artery	Emerging fibers of seventh nerve	Ipsilateral facial paralysis
			Solitary nucleus and tract	Taste loss on ipsilateral half of tongue anteriorly
			Cochlear nuclei	Hearing loss, tinnitus
			Spinothalamic tract	Contralateral sensory loss
	Mid-pons	Anterior inferior cerebellar artery and circumferential branches of basilar	Motor nucleus of fifth nerve	Ipsilateral jaw weakness
			Emerging sensory fibers of fifth nerve	Ipsilateral facial numbness

[a]Modified from Rowland LP. Clinical syndromes of the spinal cord and brain stem. In: Kandel ER, Schwartz JH, Jessell T, eds. *Principles of Neural Science*. 3rd ed. New York, NY: Elsevier; 1991:711-730.

et al found that implementation of a standardized LVO screening and transfer protocol, and the capability for cloud-based image sharing, led to significant improvements in treatment times and decreased long-term disability for patients transferred from 1 of 14 primary stroke centers to a comprehensive stroke center l. Rapid stroke and LVO assessments should be followed by activation of the acute stroke chain of care. This increases the use of intravenous tissue plasminogen activator (IV tPA) and decreases time to medical and catheter-based treatments LEVEL 1.[2]

TABLE 36.3 Prehospital Stroke Scales

Cincinnati Prehospital Stroke Scale/FAST	Yes	No
Facial droop?	☐	☐
Arm drift?	☐	☐
Speech abnormal?	☐	☐

POSITIVE SCREEN if any questions are positive.

	Points		
Los Angeles Motor Scale	0	1	2
Facial strength	Normal	Droop	—
Arms outstretched	Normal	Drifts down	Falls rapidly
Grip strength	Normal	Weak grip	No grip

POSITIVE SCREEN for stroke with high likelihood of large-vessel occlusion for a score of 2 or more.

Initial Hospital Evaluation

The American Heart Association and American Stroke Association guidelines recommend that all patients suspected of having an acute stroke or LVO be brought to a stroke-certified or thrombectomy-capable center to ensure a standardized level of care LEVEL 1.[2] Upon arrival to the emergency department, the patient must undergo rapid clinical and diagnostic evaluation in preparation for potential treatment. Initial history should be directed at defining the deficit and specific time of onset or last known time when the patient was seen normal. The clinician must then perform a rapid neurologic assessment using the National Institutes of Health Stroke Scale (NIHSS). The NIHSS (see Table 16.3) ranges from 0 to 42 with higher scores signifying greater neurologic deficit. Emergent imaging is then used to look for intracranial hemorrhage. If exam findings are suggestive, advanced vascular imaging is needed to diagnose LVO. Hospitals that provide both medical and interventional treatment for ischemic stroke often employ a streamlined process to deal with this complex diagnostic pathway in a time-sensitive manner. An LVO screening using Los Angeles Motor Scale or an NIHSS cutoff

Imaging

Computed Tomography

Noncontrast head computed tomography (NCHCT) is widely available, rapid, and extremely sensitive for detecting acute blood products. Its value in distinguishing cerebral hemorrhage from presumed ischemia has made obtaining an NCHCT a vital and necessary step in the assessment of acute stroke. Early CT findings in AIS include loss of gray-white differentiation (seen first in the insular cortex), obscuration of gray matter in the basal ganglia, and acute thrombus visualized in the proximal MCA, also known as the *dense MCA* sign (Fig. 36.7A). However, CT findings in AIS are not reliably seen until after 6 hours from stroke onset; thus, normal imaging in the setting of a clinical stroke syndrome suggests an ischemic etiology. The Alberta Stroke Program Early CT Score can be helpful in quantifying signs of acute ischemia on NCHCT (see Fig. 16.3). The Alberta Stroke Program Early CT Score and NIHSS scores can help predict functional outcome and response to treatment.

Magnetic Resonance Imaging

Although CT is the most sensitive imaging modality for acute hemorrhagic stroke, MRI, and specifically DWI, is the most sensitive modality for detecting ischemic stroke within the first 6 hours of

FIGURE 36.7 Acute ischemic stroke imaging. This figure shows the stepwise imaging approach for a patient presenting with acute onset of left-sided weakness and right gaze deviation. The initial noncontrast head computed tomography (CT) **(A)** shows early infarct signs in the right hemisphere. CT angiography **(B)** shows an absent right internal carotid artery and right middle cerebral artery (MCA). (continued)

C. CT Perfusion

Cerebral blood volume (CBV) – decreased in the deep right MCA territory

Mean transit time (MTT): prolonged in the entire right MCA territory

Cerebral blood flow (CBF): Decreased in a large portion of the right MCA territory

D. MRI

Diffusion-weighted imaging (DWI): hyperintensity in the deep right MCA territory signifying acute infarct

Fluid-attenuated inversion recovery (FLAIR): 1-y follow-up showing chronic infarct in the deep structures with relative preservation of the cortex

FIGURE 36.7 *(continued)* CT perfusion (C) shows an area of core infarct defined by a low cerebral blood volume, prolonged mean transit time, and decreased cerebral blood flow surrounded by a widespread area of tissue at risk defined by relatively stable cerebral blood volume, prolonged mean transit time, and decreased cerebral blood flow. On magnetic resonance imaging (MRI), the diffusion-weighted imaging sequence in the acute setting and the fluid-attenuated inversion recovery sequence 1 year later (D) confirmed that only the presumed core area had infarcted and not the hemisphere as a whole, probably due to good leptomeningeal collaterals.

onset (Fig. 36.7D). Despite its superior sensitivity, however, the use of MRI in the acute management of AIS is limited due to its relative unavailability in most emergency departments and the prolonged time necessary for image acquisition. Despite its superior sensitivity, small infarcts and those in the posterior circulation may not be seen on DWI, especially in the early hours after infarction. Although these issues limit its utility in the acute setting, obtaining an MRI after treatment decisions are made can be helpful in confirming the presence of ischemic stroke, identifying the specific stroke location, and helping to diagnose the stroke etiology.

Vascular Imaging

Computed tomography angiography (CTA) allows for acute evaluation of the cervical and cerebral vessels by opacifying the vasculature with IV contrast delineating any irregularities, stenoses, or occlusions (Fig. 36.7B). Magnetic resonance angiography detects flow within blood vessels allowing for visualization of vasculature and any "flow voids" that occur within them but, similar to MRI, is limited by the time necessary for image acquisition. Special MRI techniques such as vessel wall imaging and arterial spin labeling can show details of the vessel wall and flow dynamics within the vessel, but their role in the clinical setting remains investigational. Ultrasound evaluation of the carotid arteries or the proximal intracranial vasculature can provide information about the direction of blood flow and define sites of arterial stenosis or occlusion. Although vessel imaging is not recommended for all cases of AIS, its use in select patients may help in planning for interventional therapies.

Perfusion Imaging

A computed tomography perfusion (CTP) study can be performed along with CTA measuring the time to arrival and volume of contrast arriving in various areas of the brain by repeatedly scanning during a timed IV contrast injection (Fig. 36.7C). The opposite

hemisphere is used for comparison, and images are created to show relative amounts of CBF, cerebral blood volume (CBV), and mean transit time of contrast. Perfusion imaging may help differentiate the penumbra from core infarct. The penumbra retains cerebrovascular autoregulation and experiences vasodilation and recruitment of collateral vessels in response to relative hypoperfusion. It is defined by a low CBF and prolonged mean transit time with a compensatory increase in CBV caused by vasodilation. The ischemic core, in contrast, loses its physiologic ability to autoregulate and therefore has blood shunted away from it creating a relative deficit in CBV. If the penumbra further destabilizes, autoregulation fails and the area with low CBV expands.

Magnetic resonance perfusion imaging is similar to CTP and can distinguish infarcted from at-risk tissue by comparing perfusion imaging to DWI sequences, but it is more time-consuming than CTP. Perfusion imaging, in some cases automated volumetric assessment of core infarct and penumbra, is becoming standard practice in advanced stroke care centers. The CTP is particularly helpful in patients who are outside of the traditional time-based treatment window or in whom a timeline cannot be established, as in wake-up stroke LEVEL 3.[2]

ACUTE TREATMENT

Estimations based on mathematical modeling suggest that 1.9 million neurons and 14 billion synapses are lost for every minute of ischemia. Stroke expansion is usually complete within 4 to 6 hours of onset, at which point potentially salvageable areas of penumbra become irreversibly infarcted. Emergency treatment with IV tissue plasminogen activator (tPA) is the fundamental medical therapy used to achieve reperfusion. Benefit directly correlates with time to treatment with a linear relationship between shorter onset-to-needle time and improved 3-month functional outcome. Benefit levels off after 4.5 hours and the risk of hemorrhagic transformation begins to exceed the benefit of salvaging penumbral tissue at risk. Rapid onset-to-treatment time will always remain the most important factor in the treatment of AIS.

Intravenous Thrombolysis

The only currently U.S. Food and Drug Administration–approved medical treatment for AIS is IV tPA. As onset-to-treatment time increases, the effectiveness of tPA diminishes and the risk of hemorrhage increases. Optimal treatment involves the administration of tPA as quickly as possible up to 3 hours from symptom onset for most patients and 4.5 hours in a select group of patients LEVEL 2.[3,4] The original 3-hour time window is largely based on the National Institute of Neurological Disorders and Stroke (NINDS) trial from 1995, which showed that administration of IV tPA within 3 hours of symptom onset led to an improved clinical outcome at 3 months with a 13% absolute increase in good functional recovery compared to placebo despite an approximate 6% absolute risk increase in symptomatic intracerebral hemorrhage (ICH) with IV tPA. This translates to a number needed to treat of eight patients to achieve good recovery in one patient who would have otherwise had a poor outcome.

A pooled analysis of the Alteplase Thrombolysis for Acute Noninterventional Therapy in Ischemic Stroke, European Cooperative Acute Stroke Study (ECASS) I and II, and NINDS trials showed that administration of tPA up to 4.5 hours after symptom onset appeared beneficial, which prompted the ECASS III trial. The ECASS III excluded patients older than age 80 years, those with an NIHSS score higher than 25, those with a history of diabetes and prior ischemic stroke, and those on anticoagulation regardless of international normalized ratio (INR) values. An IV tPA administration within the 3- to 4.5-hour range, was associated with higher chance of favorable long-term outcome when compared to the placebo group, albeit to a milder degree than that in the original NINDS trial. The American Heart Association and American Stroke Association therefore recommend the use of IV tPA up to 4.5 hours after ischemic stroke symptom onset in patients younger than 80 years of age who are not on anticoagulation and do not have both comorbid diabetes and history of stroke LEVEL 3.[3,4] A practical protocol and checklist for IV tPA use is provided in Chapter 16.

Contraindications to Intravenous Thrombolysis

Contraindications for IV tPA are based on the inclusion criteria used in the original NINDS trial. However, these rigorous contraindications may not necessarily define the full population of patients who might benefit from tPA. **Table 16.5** shows the relative strength of various contraindications to tPA therapy based on published experience since the original NINDS trials.

Weak to Moderate Relative Contraindications

Minor symptoms, a rapidly resolving deficit, seizures, and hypo- or hyperglycemia at presentation are examples of relative contraindications. Despite these initial relative exclusions, most patients with minor or resolving deficits should in fact be considered for IV tPA treatment, as a subanalysis of the NINDS trial confirmed the benefit of tPA administration in this population. Seizure at time of presentation is also considered by most experts to be a relative rather than an absolute contraindication. The main concern here is treating a stroke mimic, although data suggest that the rate of hemorrhagic complications in stroke mimics treated with IV tPA is very low. Onset seizures are rare in AIS but do not increase the risk of hemorrhagic conversion per se. Blood glucose should be measured and corrected in all patients because hypo- or hyperglycemia can lead to neurologic deficits mimicking acute stroke, and hyperglycemia has been associated with an increased risk of hemorrhagic conversion after thrombolysis. Nonetheless, it may be reasonable to give IV tPA if the index of suspicion for a true stroke is high and glucose levels can be readily normalized during and after the treatment period.

Blood pressure higher than 185/110 mm Hg is a moderate relative contraindication to treatment. In most cases, blood pressure can be quickly controlled with a continuous IV infusion of nicardipine, labetalol or clevidipine, and IV tPA given once blood pressure is successfully lowered.

Absolute to Strong Relative Contraindications

The presence of cerebral hemorrhage on initial head CT, early infarction already involving greater than one-third of the MCA territory, or treatment beyond the 4.5-hour time window are absolute contraindications to IV thrombolysis (see **Table 16.5**). Active treatment with warfarin and an INR greater than 1.7 is also an absolute contraindication. Thrombocytopenia (platelet count less than 100,000) is a strong relative contraindication to IV tPA; in the proper circumstances, it may be reasonable to treat as long as a relative increment in hemorrhagic conversion is recognized and accepted. The use of direct oral anticoagulants, including dabigatran, rivaroxaban, apixaban, and edoxaban, are

more problematic because they do not produce reliable changes in prothrombin time (PT)/INR or partial thromboplastin time, and other assays are not readily available. The current consensus is to avoid using IV tPA and seek intra-arterial (IA) reperfusion strategies in patients who have taken a novel oral anticoagulant within 48 hours of presentation. It is important to note that tPA should never be delayed while waiting for a platelet count or INR in a patient with no suspicion of having a coagulation disturbance by history. Studies have shown that the risk of encountering clinically significant thrombocytopenia or coagulopathy in tPA candidates in whom the history did not suggest a possible abnormality was only 0.2% to 0.3%.

As many as one-third of dissection patients can present with acute neurologic symptoms from ischemic stroke. Suspected aortic dissection is an absolute contraindication to thrombolysis, as IV tPA can worsen the dissection and prove fatal. Patients with characteristic chest or back pain should therefore be screened with urgent CTA of the chest to rule out aortic dissection prior to further consideration of thrombolysis.

Complications of Thrombolysis

Hemorrhagic Conversion

Hemorrhagic conversion of the infarcted tissue bed is a known complication after stroke, and risk is significantly increased in patients treated with IV tPA. Hemorrhagic conversion is classified as hemorrhagic infarction or parenchymal hematoma (PH) depending on radiologic characteristics. Hemorrhagic infarction is defined by hemorrhagic petechiae within the stroke bed and is not associated with a worsened outcome, whereas PH is defined by blood occupying either less than 30% of the stroke bed with mild space-occupying effect (PH1) or over 30% with significant mass effect (PH2). Only PH2 is as associated with an increase in mortality. Hemorrhagic conversion usually manifests with headache, nausea, vomiting, worsened neurologic deficit, and/or altered level of consciousness. Risk factors for hemorrhagic conversion after thrombolysis include advanced age, increased onset-to-treatment time, higher NIHSS (stroke severity), hyperglycemia, and hypertension before or after tPA administration. The SEDAN score (Table 36.4) is a validated tool that can help to identify IV tPA candidates with greater than the expected 3% risk of symptomatic hemorrhagic conversion.

TABLE 36.4 The SEDAN Score for Predicting Risk of Hemorrhagic Conversion With Intravenous Tissue Plasminogen Activator[a,b]

Sugar (blood glucose level)	
• 145-216 mg/dL	+1
• >216 mg/dL	+2
Early infarct signs	+1
Dense MCA (or other vessel) sign on admission CT	+1
Age older than 75 yr	+1
NIHSS >9 points	+1
TOTAL	0-6

Abbreviations: CT, computed tomography; MCA, middle cerebral artery; NIHSS, National Institutes of Health Stroke Scale.

[a]Total scores range from 0 to 6. The approximate risk of symptomatic hemorrhagic conversion for a score of 0, 1, 2, 3, 4, or 5+, respectively, are 1%, 3%, 6%, 10%, 20%, and 30%.

[b]From Strbian D, Engelter S, Michel P, et al. Symptomatic intracranial hemorrhage after stroke thrombolysis: the SEDAN score. *Ann Neurol.* 2012;71:634-641.

Angioedema

A tPA-associated angioedema and/or anaphylaxis occurs in 1% to 5% of cases usually beginning 30 to 120 minutes after tPA infusion. Patients taking angiotensin-converting enzyme inhibitors are at higher risk, but all patients receiving tPA should be monitored closely for signs of angioedema and airway compromise. Should angioedema occur, administration of steroids, antihistamines, and/or epinephrine can be considered depending on severity and comorbidities.

Endovascular Therapies

Successful recanalization after LVO is associated with improved prognosis, and early reperfusion has been consistently shown to result in better long-term functional outcome than later reperfusion. Unfortunately, IV tPA leads to recanalization less than 50% of the time in LVO on average, with smaller and more distal clots responding more favorably compared with the large proximal clots that cause massive infarcts. One study using transcranial Doppler after IV tPA found recanalization rates for distal MCA, proximal MCA, and distal ICA locations to be 44%, 29%, and 10%, respectively. Recanalization after tPA is also dependent on clot length, with lower rates of recanalization seen for clots greater than 8 mm in length. Due to the relatively low recanalization rates seen with IV tPA in large proximal vascular occlusions, intra-arterial thrombolysis with tPA (IA tPA), mechanical thrombectomy, and sonothrombolysis with high-frequency ultrasound have all been proposed as viable adjuncts to tPA in LVO. Of these, only mechanical thrombectomy has proven unequivocally effective for use in the clinical setting.

Intra-arterial Thrombolysis

The first endovascular therapy developed for treatment of ischemic stroke was IA delivery of thrombolytics beginning in the 1990s. Initial studies showed favorable recanalization rates, which prompted the Prolyse in Acute Cerebral Thromboembolism (PROACT) II trial. In this study, 180 patients with proximal MCA occlusion within 6 hours of symptoms onset were randomized to IA prourokinase plus IV heparin versus IV heparin alone. Recanalization rates were 66% in the study group compared to 18% in the control group. Although mortality was similar in both, good functional outcome at 3 months was seen in 40% of the endovascular therapy group compared to 25% in the placebo group despite a higher rate of symptomatic ICH in the prourokinase group (10% vs 2%). Mechanical thrombectomy devices have proven to be more effective at achieving recanalization than IA tPA, although IA thrombolysis continues to be used in adjunct to these newer devices.

Mechanical Thrombectomy

The Merci device was the first cerebral clot extraction device approved for use in acute LVO. Initial small and uncontrolled studies of this corkscrew-like device demonstrated recanalization in 40% to 60% of patients, with recanalization rates improving to 70% when thrombectomy was combined with IA tPA. The second available device was Penumbra, a suction device that showed recanalization rates of up to 80% within 8 hours of stroke in the Penumbra Pivotal Stroke Trial. The newest and most effective clot extraction devices are the intrathrombus retrievable stent

devices. The Trevo and Solitaire intrathrombus "*stentriever*" devices were individually tested head-to-head with the Merci device and showed significantly higher rates of recanalization.

Corkscrew and Suction Devices

Despite evidence showing increased recanalization rates with use of endovascular techniques of mechanical thrombectomy and or administration of IA tPA, the first randomized controlled trials evaluating the efficacy of endovascular therapies for improving neurologic outcome after AIS were not published until 2013. The Interventional Management of Stroke III (IMS III) trial randomized patients who had already received IV tPA within 3 hours of stroke onset to additional endovascular therapy beginning within 5 hours of onset versus no additional treatment (IV tPA alone). The study did not show a benefit in functional outcomes at 3 months for tPA plus adjunctive endovascular therapy administered within 5 hours of stroke onset compared to tPA administration alone. The Local Versus Systemic Thrombolysis for Acute Ischemic Stroke (SYNTHESIS) trial randomized patients within 4.5 hours of stroke onset to IV tPA alone or within 6 hours of onset to endovascular intervention alone. Good functional recovery at 3 months was seen in 35% of the IV tPA group compared to 30% in the endovascular intervention group. The Mechanical Retrieval and Recanalization of Stroke Clots Using Embolectomy (MR-RESCUE), published concurrently with IMS III and SYNTHESIS, also failed to show benefit of endovascular intervention compared to IV tPA in patients with perfusion deficits determined by MRI or CTP imaging.

The negative results in these trials prompted questions regarding optimal timing of therapy, patient selection, and the role of thrombectomy devices. In IMS III, for example, the mean time from stroke onset to start of endovascular therapy was longer than 4 hours and although not reported, time to recanalization likely exceeded the 4.5 hours that is accepted as beneficial for IV thrombolysis. Similarly, in SYNTHESIS, the endovascular group received intervention 1 hour later than the group receiving IV tPA, and in MR-RESCUE, the mean time from stroke onset to groin puncture was greater than 6 hours. The IMS III and SYNTHESIS also did not confirm LVO prior to intervention, and consequently, nearly 25% of patients in IMS III randomized to the intervention group did not actually receive any intervention. For SYNTHESIS, if no LVO was seen on angiography, IA tPA was infused into the suspected vascular territory based on clinical exam, which is not likely to be an effective therapy. Finally, and perhaps most importantly, the newest retrievable stent devices were used infrequently as they were not yet available when the trials began, making it more difficult to achieve high rates of recanalization. Only 30% to 40% of patients in the intervention groups in IMS III and MR-RESCUE attained greater than 50% recanalization in affected territory compared with expected recanalization rates of 60% to 80% with the stent retriever devices.

Stentriever Technology

In 2014, a well-designed randomized trial—Multicenter Randomized Clinical Trial of Endovascular Treatment for Acute Ischemic Stroke in the Netherlands—employed more accurate patient selection measures than IMS III and SYNTHESIS and, unlike these two trials, used retrievable stent thrombectomy devices. The proportion of patients with minimal or no disability at 90 days was 33% in those treated with IA therapy and tPA compared to 19% with tPA alone: a number needed to treat of seven patients to prevent one outcome of moderate or severe disability (Table 36.5).[5] There was no effect on mortality. Mean time from stroke onset to IV tPA was 1 hour and 15 minutes and

[a]All studies except for THERAPY used CTA for confirmation of LVO.

[b]Treatment arms were IAT +/− intravenous tissue plasminogen activator (if eligible) versus best medical management except for EXTEND-IA and SWIFT PRIME, which required intravenous tissue plasminogen activator in the interventional group.

[c]THERAPY trial terminated early due to other positive trials (planned enrollment of 692 patients) and was therefore underpowered to show significant results for this outcome.

to groin puncture was 4 hours and 20 minutes. Follow-up CTA showed no residual LVO in 75% of the IA + tPA group and 33% of the tPA-only group.

In the spring of 2015, the Endovascular Treatment for Small Core and Anterior Circulation Proximal Occlusion with Emphasis on Minimizing CT to Recanalization Times, SWIFT PRIME, and four additional randomized controlled trials comparing mechanical thrombectomy to tPA alone reported superior outcomes with IA treatment (see **Table 36.5**) LEVEL 1.[6-10] The HERMES collaboration, a pooled analysis of nearly 1,300 patients from five modern thrombectomy trials, showed that mechanical thrombectomy was associated with a 14% absolute increase in patients achieving an excellent functional outcomes and independence at 3 months compared to the control group. Benefit was maintained in patients older than age 80 years and those who were treated beyond 5 hours LEVEL 1.[12] The benefits of mechanical thrombectomy in the extended time window—beyond 6 hours and as far out as 24 hours—were realized in 2018 with the DAWN and DEFUSE-3 trials LEVEL 1.[13,14] trials. Both employed advanced perfusion imaging to select for and treat patients with LVO and a significant core to penumbra mismatch. For this carefully selected subset of patients, there was a powerful treatment effect, similar to that in the traditional treatment window thrombectomy trials. The preponderance of evidence supporting endovascular therapy has resulted in national recommendations for endovascular treatment as (1) an adjunctive treatment in patients with documented LVO of onset less than 6 hours who have already received IV tPA, (2) the sole treatment for patient with LVO of less than 6 hours who have contraindications for IV tPA or are out of the 4.5-hour time window for IV tPA, or (3) the sole treatment for patients with LVO who are found to have a favorable advanced imaging profile in the 6- to 24-hour window LEVEL 1.[2,5-12] A favorable perfusion profile is a direct function of an individual's cerebral collateral circulation. Those with a complete circle of Willis, and robust leptomeningeal and extra- to intra-cranial collaterals, are more likely to maintain a slowly expanding core infarct to penumbra ratio. Good collaterals are therefore the hallmark of a good response to treatment in the extended time window and the basis for a "*tissue-based*" rather than the traditional "*time-based*" clock (Fig. 36.8).

Complications

Like IV tPA, endovascular therapy carries an increased risk of symptomatic ICH that varies depending on the technique used and timing of intervention. Although earlier IA thrombolysis studies like PROACT II reported a rate of 10%, recent studies report rates of symptomatic ICH of around 6%. Asymptomatic hemorrhage is much more common and may even signify adequate reperfusion within the ischemic territory. Other complications of endovascular therapy include thrombus fragmentation with distal embolization, device malfunction, groin hematoma, and the rare vessel rupture.

FIGURE 36.8 Cerebral collateral circulation. **A:** Panel shows a normal carotid bifurcation and hemispheric circulation. The *arrow* shows a patent anterior communicating artery, a component of a complete circle of Willis. **B:** Panel shows a proximal right middle cerebral artery (MCA) occlusion with of robust leptomeningeal *(top arrow)*, extra- to intracranial *(bottom arrow)* and deep perforating *(middle arrow)* collaterals all of which provide sufficient perfusion to the MCA territory. This patient had no deficits at the time of the encounter. **C:** Panel shows a mid-MCA occlusion with lack of robust collaterals, consistent with hemispheric hypoperfusion and resultant progression of ischemia to infarct. This patient presented with severe deficits.

CRITICAL CARE IN STROKE

Intensive care of stroke depends on a team approach and adherence to protocols that support best practices. Closed ICUs that provide around-the-clock availability of neurointensivists are important because this model has been shown to reduce costs, improve outcomes, and decrease hospital length of stay. These benefits may be the result of (1) organizational improvements, including the development of urgent interhospital transfer systems; (2) the uniform institution of best medical practices; (3) improved access to specialized neuroimaging, monitoring, and therapeutic techniques; and (4) the creation of physician and nursing care teams with special expertise in caring for neurologic patients. The use of checklists (Table 36.6) has been shown to improve outcome in stroke units and neurocritical care units.

A systematized and multidisciplinary approach to poststroke management initiated in a specialized stroke unit or neuro-ICU has been shown to minimize common complications after stroke and should be used whenever possible LEVEL 1.[2] Aside from the prevention of poststroke complications, evaluation for stroke etiology and management aimed at limiting stroke recurrence should ensue in the period immediately following AIS. For details, refer to Chapter 45: Primary and secondary stroke prevention.

Clinical Syndromes

Malignant Middle Cerebral Artery Infarction

Large hemispheric or *malignant MCA* infarction is a massive stroke that occurs as a result of ICA or proximal MCA occlusion resulting in cerebral edema that leads to herniation and death in 40% to 80% of patients without treatment. Malignant MCA infarction is essentially a hemispheric compartment syndrome, in which swelling and increased local tissue pressure leads to extension of the ischemic territory, herniation, and compressive injury of the brainstem. Patients with acute infarction involving over half of the MCA territory are at risk, whereas 95% of those with infarction affecting more than two-thirds of the MCA territory will progress to herniation. Imaging, including CT and MRI, can be used as early as 6 hours after infarction to predict malignant evolution. These patients should be managed in a neuro-ICU to allow for prompt detection of early neurologic deterioration and treatment of cerebral edema if it occurs. Monitoring of intracranial pressure is not useful because the swelling is focal, and patients can herniate from cerebral edema without developing a rise in intracranial pressure. The definitive treatment to prevent herniation and mortality is hemicraniectomy, but bolus osmotherapy with hypertonic saline and mannitol is effective temporizing measure. Therapeutic hypothermia has been tested as a treatment for malignant cerebral edema but has not been shown to improve outcome. In most patients, medical therapies should be used as a bridge to decompressive surgery and not as stand-alone therapy.

Three trials for decompressive hemicraniectomy in malignant MCA infarction have been performed, although all were underpowered to show efficacy. As they used similar inclusion criteria, a prespecified combined analysis of these trials was performed and showed an absolute risk reduction of 51% for death or severe disability and a 23% absolute increase in the proportion of patients who were alive and able to walk independently at 6 months compared with conservative medical management. These results corresponded to a number needed to treat of two patients to prevent one death and four patients to turn what would have been one death to a patient living with a moderate level of functional disability but still able to walk independently. As a result, hemicraniectomy is recommended for the treatment of malignant MCA infarction in patients younger than 60 years of age when the procedure is in line with the wishes of the patient or the patient's family LEVEL 1.[15] None of the three trials included patients older than age 60 years. A subsequent study, the Decompressive Surgery for the Treatment of Malignant Infarction of the Middle Cerebral Artery II trial, showed a mortality reduction from 70% to 33% in patients aged 61 to 82 years, but with worsened neurologic outcomes compared to younger patients LEVEL 3.[16] There was not a significant increase in the survivors with mild or moderate disability, as nearly all of the survivors were bedbound or unable to walk independently. This expected prognosis along with the premorbid functional status should be taken into account and discussed with family members prior to making any treatment decisions.

TABLE 36.6 Stroke Unit Checklist

☐ BP goal <180/105 mm Hg for 24 h if IV tPA was given
☐ BP goal <220/120 mm Hg if no IV tPA was used
☐ Serial monitoring of vital signs
☐ Serial monitoring of neurologic deficits
☐ Dysphagia screen
☐ Aspirin (by mouth or rectal)[a]
☐ Enoxaparin 40 mg SC daily (heparin 5,000 units 3 times a day if renal dysfunction)[a]
☐ Place sequential compression device.
☐ High-dose statin
☐ Neurovascular work-up: carotid and intracranial Doppler ultrasounds, CTA or MRA
☐ Cardiac workup: ECG, serial troponins, telemetry, echocardiogram
☐ Screen: hemoglobin A_{1c}, lipid panel, toxicology, urinalysis
☐ Remove Foley.

Abbreviations: BP, blood pressure; CTA, computed tomography angiography; ECG, electrocardiogram; IV tPA, intravenous tissue plasminogen activator; MRA, magnetic resonance angiography; SC, subcutaneous.
[a]Contraindicated in the first 24 hours after thrombolysis.

Cerebellar Infarction

Cerebellar infarction represents approximately 3% of total ischemic strokes. In cases of a large cerebellar infarction, cytotoxic edema in the limited compartment of the posterior fossa can lead to brainstem compression, hydrocephalus from obstruction of the fourth ventricle, and tonsillar or upward herniation. The peak period of deterioration is 72 hours, although patients may deteriorate earlier or as many as 10 days after the ischemic insult. Signs of worsening edema include drowsiness, gaze disturbance, hemiparesis, and hyperreflexia. The onset of these clinical signs is often insidious, and coma can develop rapidly without intervention, necessitating that all patient with large cerebellar infarction be closely monitored in an intensive care setting. In cases where brainstem compression or hydrocephalus appears, posterior fossa craniectomy is highly effective at preventing mortality and allowing for good functional outcome, although randomized trials have not been performed. Management with

an external ventricular drain or excision of the infarcted tissue can also effectively alleviate compression but carries the risk of upward herniation by lowering the supratentorial pressure. Thus, decompressive surgery should be the initial intervention considered in most cases.

Basilar Artery Occlusion

Basilar artery occlusion carries a mortality of up to 90% without treatment. Those who survive are often left with significant functional deficits ranging from ataxia or weakness to *locked-in* syndrome. Given its poor natural history, aggressive attempts at reperfusion, even beyond the accepted range of therapy for ischemic stroke in other locations, are often considered. Although IV tPA within 4.5 hours remains the only proven treatment option, anecdotal data show potential benefit of IA thrombolysis or mechanical thrombectomy as long as 24 hours after stroke onset. For patients with mild to moderate symptoms, IV tPA and close monitoring may be sufficient. However, for those who present with severe symptoms, IV tPA, IA tPA, and/or mechanical thrombectomy are all appropriate considerations.

Cervical Artery Dissection

Carotid and vertebral artery dissections are uncommon etiologies of stroke causing only 2% of all cases. However, they account for a much higher proportion of AIS in young patients causing 10% to 25% of all strokes in this population. The most common risk factor is cervical twisting or trauma, but presentations can be spontaneous or resulting from an underlying arteriopathy such as fibromuscular dysplasia, Marfan syndrome, or Ehlers-Danlos syndrome type IV. Clinical presentations of internal carotid dissection include facial pain, headache, neck pain, an incomplete oculosympathetic syndrome (Horner syndrome with preserved sweat response), and contralateral stroke symptoms, such as hemiparesis or aphasia. When strokes occur, they most often result from artery-to-artery embolism but can also occur in a watershed territory from arterial narrowing or occlusion of the dissected vessel.

The Cervical Artery Dissection in Stroke Study is the only randomized trial comparing management options in acute cervical artery dissection. Like several meta-analyses, it showed no difference in mortality or stroke occurrence in patients treated with antiplatelet agents versus those treated with anticoagulation. Nevertheless, anticoagulation is often used in patients with evidence of a free-floating thrombus within the lumen of the vessel, or in those with recurrent events despite treatment with antiplatelet agents. In contrast, patients with large infarcts or intracranial extension of their dissection should be treated with antiplatelet agents due to an increased risk of bleeding with anticoagulation.

Complications of Stroke

Neurologic Deterioration

Neurologic deterioration occurs in up to 40% of patients in the first 24 hours after AIS and is associated with a history of diabetes, high blood glucose concentrations, stroke severity, and early signs of edema on imaging. Although most forms of deterioration are due to progressive extension of the infarct core into surrounding penumbra, the causes of neurologic worsening are diverse and often require further investigation. All patients should undergo general and neurologic examination to determine the nature and extent of clinical change. Vital signs are important, especially because fever can cause deterioration and changes in blood pressure in either direction can have deleterious effects.

If neurologic worsening directly coincides with relative hypotension, trials of increasing cerebral perfusion can be used to confirm the presence of a blood pressure–dependent deficit. Administration of IV fluids, positioning the patient in the Trendelenburg position, or infusion of a vasopressor such as phenylephrine (starting at 20 μg/min, titrated upward to raise blood pressure by 20%) can be trialed followed by a repeat neurologic examination. If there is clinical improvement correlating to a higher mean arterial pressure, a blood pressure goal can be maintained using vasopressor agents administered under close observation in an intensive care setting. Vascular and perfusion imaging with CT or MRI may be useful at this point to evaluate for high-grade vascular stenosis and downstream perfusion/infarction mismatch.

Patients with large infarcts are more likely to develop hemorrhagic conversion, which, when symptomatic, usually presents with relatively abrupt changes in clinical signs and may be accompanied by symptoms of headache, nausea, and vomiting. Noncontrast head CT is used to evaluate for signs of hemorrhage. If a hemorrhage with associated mass effect is found, the clinician should reverse any form of anticoagulation or antiplatelet therapy (see **Table 16.4**).

If preliminary evaluations with examination, vital signs, and imaging do not reveal an etiology for neurologic worsening with depressed level of consciousness, electroencephalogram may be considered to evaluate for nonconvulsive seizure activity. Early seizures after AIS occur in approximately 5% of cases and are more common in cortical infarcts but can also occur after subcortical strokes. Although primary seizure prophylaxis is not recommended, treatment with antiepileptic agents is warranted after a seizure has occurred.

Hypertension

A *U-shaped* relationship exists between blood pressure on admission and clinical outcome, with both extremes conferring a poor outcome. The optimal blood pressure goal in AIS remains undefined. However, studies have consistently found that an acute fall in blood pressure, specifically a systolic decrease of higher than 20 mm Hg, is associated with poor functional outcome and increased mortality. Hypotension should be avoided in the acute phase of stroke, and any attempts at lowering blood pressure should be done slowly.

Current practice for those who have not received thrombolytic therapy is to allow permissive hypertension of up to 220/120 mm Hg for 24 to 48 hours, after which point antihypertensive therapy is started and slowly titrated to an extended goal toward normotension. This upper limit should be adjusted accordingly for patients with heart failure, valvular heart disease, or coronary artery disease in order to prevent any cardiac injury or complications. Similarly, in patients with hemorrhagic conversion or brain edema, blood pressure targets should be individualized at lower levels. A strict blood pressure goal of lower than 180/105 mm Hg should be maintained for 24 hours in those treated with IV tPA or mechanical thrombectomy in order to limit secondary ICH LEVEL 1.[2]

Infectious Complications

Aspiration Pneumonia

Dysphagia occurs in nearly 40% of stroke patients and is associated with a significant increase in the incidence of pneumonia. Of all the medical complications after stroke, pneumonia carries the

highest proportion of attributable risk for mortality. All stroke patients should undergo an early dysphagia screen using an objective test, such as a simple bedside water swallow test. Comprehensive evaluation by a speech-language pathologist followed by barium esophagography or videofluoroscopy may be necessary. Early recognition of dysphagia can lead to prevention techniques and therapies, such as maintaining patients in a sitting position after feeding and providing oral care, which may reduce morbidity and mortality associated with aspiration-related pneumonia. When necessary, a nasogastric or nasoduodenal feeding tube should be placed for nutritional support and medication administration. If prolonged dysphagia is expected, a percutaneous endoscopic gastrostomy allows for extended nutritional support.

Urinary Tract Infection

Urinary tract infection occurs in 10% to 15% of stroke-related hospitalizations and is associated with worsened neurologic and functional outcomes. Risk factors for urinary tract infection include increasing age, female sex, poststroke disability, urinary retention, and, most importantly, urinary catheterization. Avoiding urinary catheterization and early removal of urinary catheters reduces the risk of catheter-associated urinary tract infections.

Venous Thromboembolism

Patients with stroke are at high risk for developing deep vein thrombosis (DVT) due to hemiparesis and immobility. Studies done in the absence of pharmacologic DVT prophylaxis suggest that DVT occurs in as many as 40% to 50% of hemiplegic patients within 2 weeks of stroke onset. The associated risk of pulmonary embolism is 15% in untreated patients, which can lead to early death following AIS.

Although unfractionated heparin has been proven effective for DVT prophylaxis, the Prevention of VTE After Acute Ischemic Stroke with Low-Molecular Weight Heparinoid Enoxaparin trial showed that enoxaparin 40 mg daily was more effective at preventing DVT than unfractionated heparin administered twice daily. Pneumatic sequential compression devices are also effective when used independently and provide an added benefit when used in addition to pharmacologic DVT prophylaxis. Early mobilization is also effective in preventing DVT and provides added benefits in functional recovery. Current guidelines recommend pharmacologic DVT prophylaxis in all stroke patients, unless there is a substantial risk of bleeding that would outweigh the potential benefits, in which case nonpharmacologic options should be employed LEVEL 2.[17] Pharmacologic DVT prophylaxis should also be held for 24 hours after tPA administration.

STROKE OUTCOMES

Outcome after stroke is defined as the level of functional impairment or death months to years after the insult. Stroke is now the fifth leading cause of death in the United States and the leading cause of disability among adults. Accurately predicting a patient's outcome can aid in deciding the best management approach and help establish appropriate expectations for quality of life. Using retrospective data from various cohorts, a number of prediction models have been established to predict long-term stroke outcomes at the time of the acute stroke. Stroke severity, which can be assessed with the NIHSS, and patient age have consistently proven predictive of outcome. Specific exam features that have been cited include upper extremity paralysis and inability to walk independently. Others frequently cited factors include infarct volume, fever, diabetes, and congestive heart failure (Table 36.7). Outcome after ischemic stroke can be improved by care in a dedicated stroke unit, using a systematic approach to minimizing preventable medical complications, and instituting early rehabilitation.

Transient Ischemic Attack 37

Setareh Salehi Omran and Jose Gutierrez

KEY POINTS

1. Transient ischemic attack (TIA) is a transient episode of neurologic impairment caused by focal cerebral or retinal ischemia without any permanent infarction.
2. Authentic TIAs are associated with a high risk of subsequent stroke within the acute period. The stroke risk in the first 2 days after a TIA is around 5%.
3. The best validated tool for assessing the short-term risk of ischemic stroke after TIA is the $ABCD^2$ score. The score relies on patient factors, presenting features, and duration of symptoms. A higher score is associated with a greater risk of subsequent stroke.
4. Immediate evaluation and management of TIAs may reduce the risk of a subsequent stroke. Evaluation includes urgent brain and neurovascular imaging, identification of vascular risk factors, and cardiac work up. TIA treatment is similar to ischemic stroke management and is based on the identified etiology.

INTRODUCTION

A transient ischemic attack (TIA) is an episode of neurologic impairment caused by focal cerebral or retinal ischemia without any permanent infarction. Although classically defined as less than 24 hours in duration, studies have challenged the time-based definition of TIA by illustrating that most TIAs are brief and less than 1 hour in duration. In fact, attacks typically last for only a few minutes to an hour. Despite the short period of ischemia, there is still a risk of permanent tissue infarction, with nearly half of all TIAs causing visible infarction on brain imaging. This has led to a shift from a time-based to a tissue-based definition of TIA, with TIA consisting of neurologic impairment in the absence of any imaging findings of infarction.

Although often referred to as a *ministroke*, a TIA may have ominous implications. TIA patients are at an increased risk for a subsequent ischemic stroke within the short and long term. Urgent recognition, evaluation, and treatment can aid in reducing the risk of future ischemic events in this population.

EPIDEMIOLOGY

Around 240,000 TIAs occur each year in the United States, with an incidence ranging from 68 to 83 per 100 000 residents. Around 2% of the U.S. population has experienced a TIA. Ethnic and sex differences exist in the incidence of TIAs, with men and blacks more commonly affected than women and whites.

PATHOBIOLOGY

TIAs can occur through several different mechanisms. The three main mechanisms are embolic, lacunar or small-artery disease, and low-flow TIAs. TIAs caused by embolism—from the heart, aorta, or proximal large-vessel atherosclerotic plaque or dissection—last longer because the embolus transiently occludes a distal arterial branch before spontaneously dissolving. Small-artery TIAs result from lipohyalinosis and arteriolosclerosis of penetrating arteries, such as the lenticulostriate branches of the middle cerebral artery, or penetrators of the vertebral and basilar arteries. TIAs can be caused by low flow distal to a severe carotid or vertebrobasilar stenosis; such TIAs are typically brief and stereotyped, presenting with repeated episodes of the same syndrome.

Less common mechanisms include intracranial or extracranial arterial dissection causing a low-flow state or distal embolism; vasospasm-related TIA from subarachnoid hemorrhage or reversible cerebral vasoconstrictive syndrome; hyperviscosity syndromes (polycythemia, sickle cell anemia, thrombocythemia); cerebral venous thrombosis; bacterial endocarditis; and temporal arteritis. Permanent small-artery occlusion with evidence of a small infarct on magnetic resonance (MR) diffusion-weighted imaging (DWI) can result in a transient deficit lasting up to 24 hours before resolving ("cerebral infarction with transient symptoms").

DIAGNOSIS

Symptoms vary depending on the pathophysiologic mechanism and the involved arterial territory. Embolic TIAs can occur from artery-to-artery embolism, cardioembolism, or an undetermined embolic source and can affect the anterior or posterior circulation. Anterior circulation embolic TIAs can affect the parenchyma or retinal arteries. Central retinal artery—a branch of the ophthalmic artery and ultimately the internal carotid artery—involvement causes transient monocular blindness, otherwise known as *amaurosis fugax*. Amaurosis fugax presents as blurring or darkening of vision in one eye, peaking within a few seconds (sometimes as if a curtain had descended) and usually clearing within minutes. In some patients, embolic particles (Hollenhorst plaques) are seen in retinal artery branches; in others, spasm of the central retinal artery and its branches is observed. Apart from transient monocular blindness, anterior circulation TIAs can also affect the parenchyma and produce varying combinations of limb weakness and sensory loss, aphasia, hemineglect, and homonymous hemianopia. Posterior circulation TIAs cause symptoms referable to the occipital cortex (visual field loss or cortical blindness), brainstem (cranial nerve and long-tract symptoms, sometimes crossed or bilateral), or cerebellum (ataxia, gait instability).

Lacunar or small-artery TIAs result from stenosis of one of the penetrating arteries of the middle cerebral artery, basilar artery, vertebral artery, or the circle of Willis. These TIAs produce "lacunar syndromes" such as pure hemiparesis or pure hemisensory loss. Lacunar or small-artery TIAs can consist of brief, stereotyped clinical symptoms. A particularly concerning presentation of lacunar TIAs is the *capsular warning syndrome*, which consists of multiple brief attacks of motor impairment resulting from hemodynamic changes in diseased small lenticulostriate or basilar penetrating arteries. Capsular warning syndromes have been shown to progress to early subsequent lacunar infarction in 42% of cases.

Low-flow TIAs can result from severe stenosis of a large artery, such as the proximal internal carotid artery, proximal middle cerebral artery, or vertebrobasilar junction. Unlike embolic TIAs, low-flow TIAs usually last minutes in duration and are often recurrent, with episodes occurring as frequently as a few times a day to several times in a year. The episodes can be stereotyped due to repetitive ischemia to the brain area supplied by the artery distal to the stenosis. Indeed, recurrent TIAs of the same type are more likely to be the result of perfusion failure due to critical narrowing or occlusion of the involved artery than from embolism. Common symptoms of low-flow TIAs from significant internal carotid artery or middle cerebral artery stenosis include recurrent episodes of contralateral hemiparesis or hemisensory loss, neglect, and aphasia. Low-flow TIAs from vertebrobasilar stenosis can cause a myriad of symptoms including dizziness, diplopia, dysarthria, and bilateral or unilateral leg and arm weakness or numbness. TIAs of this hemodynamic type may occur only during upright posture or during transient hypotension or cardiac arrhythmia.

TIAs can also manifest with clinical symptoms that mimic seizures and movement abnormalities, such as paroxysmal dyskinesias, tremors, ataxia, limb dystonia, and myoclonic jerking. Similarly, critical carotid artery stenosis or occlusion can cause low-flow TIAs that resemble seizure-like episodes. These "limb-shaking TIAs" consist of coarse irregular shaking of an arm or leg lasting seconds to a minute that can be precipitated by a change in posture. Additionally, episodes that resemble "drop attacks" may be seen in people with an anatomic variant consisting of both anterior cerebral arteries supplied by a single, severely stenotic internal carotid artery.

Subclavian steal syndrome can also produce transient neurologic deficits resulting from vertebrobasilar ischemia. In the subclavian steal syndrome, stenosis of the subclavian or innominate artery proximal to the origin of the vertebral artery leads to diversion of anterograde flow via the contralateral vertebral artery retrograde down the ipsilateral vertebral artery distal to the occlusion, depriving the basilar artery of blood flow. Subclavian steal syndrome can cause brainstem, cerebellar, or even cerebral symptoms, often manifested during exertion and sometimes accompanied by symptoms of arm claudication.

The diagnosis of TIA may be difficult to ascertain and is based mostly on the clinical features of the event. Since most patients present after symptom resolution, a detailed clinical history must be obtained to determine if the pattern of involvement is consistent with an ischemic insult. Typical TIAs are characterized by transient neurologic events that localize to a single vascular territory within the brain. However, many patients present with more ambiguous symptoms, such as staggering or drop attacks; dizziness, lightheadedness, or syncope; vertigo; fleeting diplopia; transient amnesia; atypical visual disturbance in one or both eyes such as flashes, distortions, or tunnel vision; a heavy sensation or "tiredness" in one or more limbs; and fixed or transient paresthesias of limbs or midline structures (eg, tongue numbness). Although these atypical symptoms are more commonly due to other causes, TIAs should be on the differential, particularly in patients presenting with brainstem symptoms. In evaluating such cases, a wide differential diagnosis of TIA needs to be considered, including migraine, cardiac arrhythmia, seizures, hypoglycemia, compressive neuropathy, conversion, and neurosis.

Although TIAs are defined in terms of their clinical reversibility and are presumed to signify ischemia too brief or incomplete to cause infarction, imaging demonstrates appropriately located infarcts in around half of cases. DWI-detected abnormalities are especially likely when symptoms last more than an hour, and those lasting longer than 3 hours show infarcts in 70% of cases. Symptom duration of more than an hour, aphasia, and motor deficits have each independently been associated with increased likelihood of DWI-detected abnormalities. Of the three symptoms, patients with a DWI-detected abnormality were almost 10 times more likely to have symptom duration of more than an hour and 16 times more likely to have experienced transient motor deficits. Some investigators therefore believe that the definition of TIA should be changed from a clinical description to a tissue-based definition, with TIAs indicating brief episodes—typically less than 1 hour—without imaging evidence of acute infarction (either on computed tomography or on magnetic resonance imaging). This is supported by evidence that neurologic deficits reemerged after giving intravenous midazolam to TIA patients whose initial deficits had resolved within 24 hours and who did not have evidence of infarction on DWI, suggesting that TIA may cause a structural lesion.

MANAGEMENT

TIAs require urgent evaluation because early implementation of secondary stroke prevention strategies following a TIA can lead to 80% reduction in future risk of stroke LEVEL 1.[1] When evaluating a TIA, a detailed clinical history and diagnostic workup is obtained to determine the exact TIA mechanism. The initial evaluation typically includes urgent brain and neurovascular imaging, identification of vascular risk factors, and cardiac evaluation (Table 37.1) LEVEL 1.[1] The secondary stroke prevention strategies depend on the stroke etiology and include revascularization for symptomatic carotid artery stenosis, anticoagulation for atrial fibrillation, management of hypertension, initiation of an antiplatelet agent and a statin, and lifestyle modifications LEVEL 1.[2]

All patients with a TIA should be on an antithrombotic agent, whether it is an anticoagulant for atrial fibrillation or an antiplatelet. Recently published data supports the short-term use of dual antiplatelet therapy for stroke prevention after a TIA LEVEL 1.[3,4] The largest international randomized controlled trial showed that a combination of aspirin and clopidogrel for 90 days after a TIA or a minor ischemic stroke was associated with a lower risk of recurrent major ischemic events but a higher risk of major hemorrhage than aspirin alone. The benefit of dual antiplatelet therapy was greatest immediately after the TIA, whereas the risk of hemorrhage increased over time. Current secondary stroke prevention guidelines state that treatment with dual antiplatelet therapy within 24 hours from event can be beneficial for secondary stroke prevention up to 90 days from

symptom onset. Patients with TIA of atherosclerotic origin are also recommended to be on high-intensity statin therapy, such as atorvastatin 80 mg LEVEL 1.[5] Further treatment strategies are identical to secondary prevention in patients diagnosed with acute ischemic stroke and are discussed in Chapter 36.

The decision to admit TIA cases or treat as an outpatient depends on several factors. Patients who are at high risk for subsequent stroke and those that cannot undergo the emergent workup within 48 hours of symptoms may be admitted for inpatient management.

OUTCOME

TIAs are associated with a high risk of subsequent stroke. In 1,707 patients presenting with TIA to an emergency department, 10% had a stroke within the next 90 days, and in half, the stroke occurred within the first 48 hours of the TIA. Retinal TIAs had about half this rate of stroke (5% within 90 d). In four European studies combining 2,416 patients who presented with ischemic stroke, 15% to 26% of ischemic strokes were preceded by a TIA and 43% of TIAs occurred within 7 days of the stroke.

Methods that can reliably assist with acute stroke risk assessment after a TIA can aid in patient triage. The best validated tool for assessing the short-term risk of ischemic stroke after TIA is the $ABCD^2$ score. $ABCD^2$ score relies on patient factors, presenting features, and duration of symptoms to assign a score of 0 to 7 (Table 37.2). The score determines the 2-day risk of stroke as either high (score 6-7), moderate (score 4-5), or low risk (score 0-3). Additionally, a higher score implies a higher 90-day risk of stroke. This highly validated scoring system is recommended for use in determining early stroke risk by the national guidelines.

Accumulating evidence suggests that the presence of an acute infarct on computed tomography or magnetic resonance imaging after a TIA is associated with a higher risk of early subsequent stroke. This was shown in a large multicenter study of early risk

of recurrent stroke after TIA using $ABCD^2$ score, subcategorized as tissue-positive or tissue-negative on imaging, where the risk of recurrent stroke rates at 7 days were significantly higher in patients with DWI-positive compared to DWI-negative TIAs (Table 37.3). Attempts to increase the predictive value of the $ABCD^2$ score have been proposed, with additional scale items including the presence of more than one TIA ($ABCD^3$), DWI-positive image, or the presence of greater than 50% carotid stenosis ($ABCD^3$-I) or intracranial arterial stenosis ($ABCD^3$-I[c/i]). Each of these scores adds a small degree of incremental predictive value compared to the original $ABCD^2$ score at the expense of simplicity. For clinical use and ease of communication, we recommend use of the standard $ABCD^2$ score while recognizing that multiple TIA events, cerebral infarction with transient symptoms, or evidence of significant extracranial or intracranial stenosis further increases the 90-day stroke risk.

Crescendo TIAs—two or more attacks within 24 hours—should be considered a medical emergency. Particularly concerning is the *capsular warning syndrome* and its high risk of subsequent lacunar infarction. Asymptomatic coronary artery

disease is especially common in patients with carotid stenosis and should be checked for. The overall risk of stroke, myocardial infarction, and vascular death remains high for at least 10 to 15 years in patients with a history of TIA.

Hypoxic-Ischemic Encephalopathy 38

Sachin Agarwal and Alexandra S. Reynolds

KEY POINTS

1. Comatose adult survivors of cardiac arrest should undergo therapeutic hypothermia between 32°C and 36°C for shockable rhythms with out-of-hospital cardiac arrest, nonshockable rhythms, and in-hospital cardiac arrest.
2. Studies involving cellular, animal, and human models suggest that therapeutic hypothermia has the potential to mitigate reperfusion-related secondary injury after cardiac arrest.
3. Delayed and multimodal neuroprognostication schemes are highly recommended.
4. Both sedation and therapeutic hypothermia alone and in combination have been shown to affect neuroprognostic markers of cardiac arrest to varying degrees.
5. Survivors of cardiac arrest experience long-term "extra-cardiac sequelae," that is, cognitive, functional, and psychosocial deficits.

INTRODUCTION

Hypoxic-ischemic encephalopathy (HIE) is a term used to describe cerebral dysfunction after a global insult to the brain. Mechanisms of such damage include prolonged interruption of blood flow and/or oxygen, most commonly after cardiac arrest.

EPIDEMIOLOGY

Approximately 630,000 cardiac arrests occur in the United States per year with an overall 14% survival to discharge. Despite an increased survival from all-rhythm cardiac arrest, the mortality is at least 50% in those who have survived to the hospital admission, and overall disease-specific mortality is around 90%. Brain injury alone is the primary cause in 68% of patients. Among all out-of-hospital cardiac arrest patients between 2000 and 2006, patients who found in asystolic arrest had the worst outcomes (1% survival to discharge and 0.5% 30-d survival), whereas those with shockable initial rhythm (ventricular fibrillation or pulseless ventricular tachycardia) had the best outcomes (15%-20% survival to discharge). Those with pulseless electrical activity fell somewhere in the middle (5%-8% survival to discharge). Utstein bystander patients (witnessed by a bystander with an initial shockable rhythm and received some bystander intervention [cardiopulmonary resuscitation and/or automated external defibrillator application]) could have a survival rate as high as 38.2%. In general, the faster the return of spontaneous circulation, the better the outcome.

These numbers do not capture the neurologic morbidity associated with cardiac arrest. Those who survive may still have significant neurologic and psychosocial deficits including cognitive dysfunction such as memory problems, difficulty with activities of daily living, and a large group of cardiac arrest survivors will experience personality changes, depression, anxiety, and post-traumatic stress disorder. Furthermore, a proportion of patients will ultimately remain in minimally conscious or persistent vegetative states. The true proportions are unknown because of high rates of withdrawal of care in patients who remain comatose after a cardiac arrest leading to a "self-fulfilling prophecy."

PATHOBIOLOGY: CAUSES OF HYPOXIC-ISCHEMIC ENCEPHALOPATHY

Cardiac Arrest

Cardiopulmonary arrest is a complex process that causes diffuse damage to the brain. The initial mechanisms of damage include hypoxemia and hypoperfusion due to circulatory arrest. However, as the cardiac arrest progresses, damage is caused by resultant hypoglycemia, acidosis, and toxin accumulation (see following text). The model of cardiac arrest resuscitation involves three time-sensitive ischemic-reperfusion phases, including electrical, circulatory, and metabolic. Although rapid reperfusion is needed after ischemia, it can also paradoxically contribute to tissue injury and destruction. Various mechanisms of cell death, including necrosis, apoptosis, and autophagy-associated cell death, have been implicated. Tissue necrosis results in swelling, and this is exacerbated by rebound hyperemia from reperfusion as well as progression of the inflammatory cascade. On a molecular level, reintroduction of glucose causes formation of nitric oxide and oxygen free radicals that can induce DNA damage and consumption of NAD+ leading to a second round of cell death. Studies involving cellular, animal, and human models suggest that therapeutic hypothermia (TH) has the potential to mitigate these deleterious processes (**Table 38.1**) even after a period of ischemia. Models where hypothermia was initiated before reperfusion have resulted in the most cellular protection.

Prolonged Hypotension

Hypotension results in preferential injury to parts of the central nervous system that lie in between vascular distributions. Areas supplied by narrowed arteries are also at risk for hypoperfusion in low-flow states like carotid stenosis or in heart failure with low cardiac output. Low cerebral blood flow results in patchy ischemic infarctions. Watershed areas in the brain affected by hypotension include the cortical border zones between the anterior cerebral and middle cerebral arteries and middle cerebral and posterior

TABLE 38.1 Mechanisms of Neuroprotection With Therapeutic Hypothermia

Metabolic	Decreased cerebral metabolism (6%-10%/°C below 38°C) Inhibition of mitochondrial injury and dysfunction Decreased production of toxic metabolites and free radicals
Neuroinflammatory	Decreased generation of inflammatory proteins Decreased release of glutamate and decreased neuroexcitotoxicity
Vascular	Decreased vascular permeability and edema Decreased cerebral thermo-pooling, reducing local hyperthermia
Cellular	Decreased ion pump dysfunction and decreased intracellular calcium influx Decreased cell membrane leakage and cytotoxic edema Decreased apoptosis and proteolysis
Other	Decreased spreading depression-type depolarizations Suppression of epileptic activity Decreased coagulation activation with formation of fewer microthrombi

cerebral arteries or internal border zone areas in the periventricular white matter or the deep structures supplied by the recurrent artery of Heubner and the anterior choroidal and lenticulostriate arteries. In the spinal cord, the anterior portion of the midthoracic distribution is considered to be the watershed region; however, one study showed disproportionate damage to the lumbosacral spinal cord after prolonged hypotension and/or cardiac arrest.

Hypoxia

Pure hypoxic hypoxia can occur in the absence of circulatory breakdown, in the case of aspiration, hanging/strangulation, or drowning. Hypoxic damage to the brain occurs solely due to decreased partial pressure of blood oxygen and results in a lesser degree of injury than combined hypoxic-ischemia. However, prolonged hypoxia will progress to cardiac arrest. Once oxygen supply to the brain is interrupted, adenosine triphosphate stores only last for minutes. After energy-dependent membrane ion transport starts to fail, damaged cells release excitotoxic glutamate, intracellular calcium begins to accumulate and activates proteases and phospholipases, and damage is propagated via inflammatory cascades. Intracellular influx of calcium in surrounding areas leads to diffuse cell death. The areas particularly susceptible to hypoxic damage are hippocampal CA1 neurons, thalami, cerebellar Purkinje cells, and cortical pyramidal cells in layers 3, 5, and 6. Among the cortical areas, perirolandic areas are most vulnerable because of the high concentration of *N*-methyl-D-aspartate receptors. White matter injury also occurs because of damage to oligodendroglial cells.

Carbon Monoxide Poisoning

Carbon monoxide (CO) primarily exerts harmful effects to the brain by causing hypoxemia in a so-called anemic-histotoxic hypoxia. As in hypoxic hypoxia, preservation of circulation portends a lesser damage to the brain. The CO preferentially binds to heme proteins and displaces bound oxygen because of its greater affinity for hemoglobin. The CO thus limits oxygen-carrying capacity of blood and impairs mitochondrial function of the tissues attempting to use oxygen, resulting in a hypoxic and acidotic state. Ultimately, CO poisoning causes intravascular and intracellular oxidative stress, inflammation, and apoptosis. The cortical laminae and basal ganglia are particularly prone to damage. Additional reports of delayed demyelination in the centrum semiovale have been published. In severe cases, cardiac toxicity can occur resulting in hypotensive brain injury as well.

Cyanide Poisoning

Cyanide poisoning causes metabolic failure by inhibiting oxidative phosphorylation. It results in direct metabolic damage to the brain but ultimately causes mixed injury due to early cardiac failure. Cyanide impairs oxidative phosphorylation by inhibiting the mitochondrial cytochrome oxidase a_3 complex. Mitochondria are unable to produce adenosine triphosphate and increased glycolysis occurs, quickly resulting in a metabolic acidosis as pyruvate is reduced to lactate. Coronary artery vasoconstriction occurs, and cardiac output decreases suddenly, causing hypotension and cardiac shock. The brain is damaged not only from this hypotension but also from metabolic failure on a cellular level.

Profound Hypoglycemia

Glucose is the primary source of energy for the brain in both adults and infants, and prolonged or repeated hypoglycemic episodes can therefore cause significant injury to the brain. Concurrent hypoglycemia also exacerbates the damage caused by hypoxemia. Brain damage usually occurs once serum glucose levels fall below 20 mg/dL. Mechanisms of cell death with hypoglycemia are similar to hypoxia, including excitotoxic glutamate and aspartate release and involvement of *N*-methyl-D-aspartate receptors. More recent studies have shown that activation of poly(ADP-ribose) polymerase 1, release of zinc from nerve terminals, and activation of calcium-dependent protease calpain also contribute to neuronal death. Furthermore, depolarization of the mitochondrial membrane leads to apoptosis. The parts of the brain most sensitive to low-glucose levels are the hippocampus (CA1, CA3, and dentate gyrus), caudate, putamen, and insular cortex.

CLINICAL FEATURES

The clinical manifestations of HIE can range from mild changes in cognition to coma. Damage to the hippocampus can result in memory deficits. Damage to the basal ganglia can present as a variety of movement disorders. Thalamic damage can result in a wide variety of symptoms from sensory changes to dementia or coma. Damage to the Purkinje cells results in cerebellar dysfunction. Cortical damage can result in inattentiveness, executive dysfunction, or aphasia. Because of the resistance of the deep gray matter of the brainstem to anoxic injury compared with the neocortex, HIE often results in coma with preservation of brainstem reflexes. However, brain death can occur with prolonged hypoxic-ischemic injury.

Watershed injury in the brain can manifest as proximal greater than distal extremity weakness and ultimately spasticity ("man-in-a-barrel syndrome"). Watershed injury to the spinal cord results in an "anterior cord syndrome" or Beck syndrome, including motor paralysis below the level of the lesion, loss of pain and temperature but intact proprioception and vibratory sensation, and loss of bowel and/or bladder control.

Lance-Adams syndrome, or posthypoxic action myoclonus, can occur several days after recovery from hypoxic injury to the brain.

The rare syndrome of delayed posthypoxic leukoencephalopathy (DPHL) following seemingly full recovery from a comatose state can occur days to weeks after the initial insult. The onset is usually insidious and can manifest as personality changes, irritability, inattentiveness, confusion, and memory problems. This can progress to include extrapyramidal motor symptoms and, in some cases, eventually coma or death. Those patients who survive stabilize to one of two ultimate syndromes: either parkinsonism with hallucinations or odd behaviors or akinetic mutism. A DPHL may occur as a result of any cause of HIE mentioned earlier but is most often seen in cases of acute CO poisoning or opioid overdose. The main histopathologic patterns seen in this syndrome are demyelination in the centrum semiovale and necrosis of the cortical laminae and basal ganglia, which correlate with brain magnetic resonance imaging (MRI) features. Severity and persistence of DPHL sequelae have been correlated to the presence and persistence of low signal intensity on the apparent diffusion coefficient (ADC) map on cranial MRI.

DIAGNOSIS

Imaging

A *computed tomography head* is usually normal immediately after hypoxic-ischemic insult. In severe injury, there can be evidence of loss of the gray-white junction within hours (Fig. 38.1A). After 24 to 48 hours, linear hyperdensities outlining the cortex develop, corresponding to laminar necrosis of the cortex. After days, the "reversal sign" develops where cerebral white matter appears hyperdense than cortical gray matter. Pseudosubarachnoid hemorrhage can also occur when the falx cerebri and tentorium cerebelli appear hyperdense as compared to the adjacent injured parenchyma (Fig. 38.1B).

An *MRI brain* is the earliest way to visualize damage, as early cytotoxic edema can be visualized on diffusion-weighted imaging (DWI) and can be quantified using the ADC (Fig. 38.1C-G). Importantly, DWI and ADC changes may not be apparent early on, and thus, early imaging may underestimate the injury burden. Moreover, there may be attenuation of ADC values for every 1°C decrease in body temperature. The DWI sequences can pseudonormalize by 7 days, but T2 hyperintensities on fluid-attenuated inversion recovery sequences develop after the first week. The damage is most often symmetric and corresponds in location to the neuronal subtypes that are preferentially damaged (see "Pathobiology: Causes of Hypoxic-Ischemic Encephalopathy" section). With time, focal laminar necrosis can be seen due to deposition of blood products (see Fig. 38.1E). In one small study, changes occurring over time within the same patient were analyzed. The location of the injury shifts with time from the initial hypoxic-ischemic event, starting in the cerebellum and

FIGURE 38.1 Imaging findings after hypoxic-ischemic encephalopathy. Computed tomography scan done 12 hours **(A)** and 10 days **(B)** after a near-drowning episode. **A:** There is diffuse loss of gray-white matter differentiation and severe global cerebral edema. There are bilateral, but right greater than left, hypodensities of the basal ganglia. **B:** The diffusely attenuated white and gray matter result in a pseudosubarachnoid hemorrhage appearance of the relatively hyperdense dura. Diffusion-weighted imaging **(C)** and apparent diffusion coefficient **(D)** sequences of a magnetic resonance imaging done 2 days after a primary respiratory arrest showing restricted diffusion in the bilateral hippocampi *(arrows)* and diffusely throughout the cortex. **E:** Susceptibility-weighted imaging sequence in coronal section done 7 days after a pulseless electrical activity arrest showing areas of laminar necrosis in the posterior parietal lobes *(arrows)*. **F:** Fluid-attenuated inversion recovery sequence 10 days after cardiopulmonary arrest only showing mild swelling and indistinctness of the gray-white junction in the bilateral parietal lobes *(arrows)*. **G:** Diffusion-weighted imaging sequence of a magnetic resonance imaging done 11 days after a pulseless electrical activity arrest resulting from a type A aortic dissection. There are scattered foci of restricted diffusion along the anterior cerebral and middle cerebral arteries and middle cerebral and posterior cerebral arteries border zones, more prominent on the right, consistent with watershed infarct.

basal ganglia in days 1 and 2, moving to the cortex around days 3 to 5, and involving subcortical white matter on days 6 to 12. Pronounced hippocampal abnormalities on DWI—the so-called bright hippocampus sign—has been associated with extremely poor outcomes (see Fig. 38.1C,D). In the case of DPHL, MRI findings are pathognomonic, with diffuse T2 hyperintensities predominantly in the dorsal frontal and parietal lobes. Whether hypothermia has any effect on resting state neural networks, fractional anisotropy on diffusion tensor imaging or any metabolites measured via magnetic resonance spectroscopy is unknown.

Somatosensory-Evoked Potentials

A noninvasive way to evaluate the functioning of the somatosensory system in a comatose patient is by performing evoked potentials. There are multiple types of evoked potentials including auditory and visual; however, somatosensory-evoked potentials (SSEPs) are most commonly used after a hypoxic-ischemic event or cardiac arrest. The SSEPs are done by providing a transcutaneous electrical stimulation along a peripheral nerve, most commonly the median nerve. The impulse is then tracked as it travels up the peripheral nerve to the elbow (N5), Erb point in the brachial plexus (N9), the posterior column of the midcervical cord (N13), and ultimately to the contralateral primary sensory cortex (N20). In cases of significant cortical damage, the N20 can be absent (Fig. 38.2).

Electroencephalography

The 2006 American Academy of Neurology practice parameters emphasized the importance of identifying electrographic seizures and burst suppression for prognostication, but minimal data was available at that time. In last few years, there have been many studies describing the evolution of electroencephalography (EEG) during hypothermia and after rewarming. The occurrence of seizures more in the first 24 hours, that is, during hypothermia phase, was to be an unexpected observation. Therefore, many experts recommend early and prolonged EEG monitoring. Most studies have confirmed an incidence of seizures in 25% of patients, and status epilepticus at any point during the hospital course is thought to be a bad prognostic indicator. However, patients have achieved good outcomes after seizures were detected and treated aggressively. The most common finding on EEG is generalized periodic discharges that are also known to be a precursor of seizures and thus poor outcomes, but more systematic evaluation of different patterns needs to be done. The EEG background features like continuity and reactivity have also been shown to be predictive of outcomes, that is, persistence of continuous background and EEG reactivity in first few days of the event is associated with good recovery. Because sedation is known to affect the EEG background and in the absence of any studies assessing its effect on reactivity, the most recent international consensus for EEG reactivity reporting recommended that information on analgesics and sedatives be reported when testing EEG reactivity in cardiac arrest patients. Further research in this area is warranted, and eventually, inclusion of appropriate, well-studied EEG patterns should be a part of multimodal prognostication paradigm.

TREATMENT

General Concepts

Intracranial pressure (ICP) can increase after cardiac arrest both because of reflex hyperemia postcardiac arrest and because of global cerebral edema in cases of significant global injury. High ICP and low cerebral perfusion pressures are associated with poor outcomes. The ICP also increases with seizure activity.

Hyperoxia is correlated with worse outcomes in humans. Each 100 mm Hg increase in Pa_{O_2} above the normal level of 100 mm Hg is associated with 24% increased risk of mortality. Unnecessary increases in the fraction of inspired oxygen should

FIGURE 38.2 Median nerve somatosensory-evoked potentials. **A:** The normal somatosensory-evoked potential tracing including the N5 waveform at the elbow, N9 at Erb point, N13 at the cervical cord, and N20 at the contralateral sensory cortex. **B:** An absent N20 after hypoxic-ischemic injury from cardiac arrest. (Chiota NA, Freeman WD, Barrett KM. Hypoxic-ischemic brain injury and prognosis after cardiac arrest. *Continuum [Minneap Minn]*. 2011;17[5 Neurologic Consultation in the Hospital]:1094-1118.)

be avoided. The goal for $PaCO_2$ should be on the higher end of normocapnia, as lower ends of the threshold are associated with decreased cerebral blood flow.

Seizures

With cortical damage comes the potential for development of complex, evolving epileptiform discharges and/or seizures. Early detection and treatment of seizures is paramount to prevent further brain damage. Myoclonic status epilepticus, characterized as a poor prognostic marker in pre-TH era, has been questioned by more recent small studies and case reports. The definition involved spontaneous, unrelenting, generalized, multifocal myoclonus involving face, limbs, and axial musculature, but no EEG correlate was needed for the diagnosis. An EEG monitoring with a trial of paralytic to remove muscle artifact, if necessary, should be attempted, and if the patient is found to be in electrographic status epilepticus, they should be treated aggressively.

Therapeutic Hypothermia

Beginning in the 1950s, cardiothoracic surgeons used moderate hypothermia (28°C-32°C) during cardiac surgery to prevent brain ischemia. The idea of cooling after unexpected cardiac arrest and subsequent resuscitation, however, was not seriously pursued until the early 1990s, when animal studies became popular. In 2002, two randomized controlled trials were published suggesting that patients in cardiac arrest with an initial rhythm of ventricular fibrillation who remained comatose after return of spontaneous circulation had better outcomes after mild TH to 32°C to 33°C for 12 to 24 hours LEVEL 1.[1,2] Recent study showed that there is no benefit to cooling to 33°C when compared to 36°C LEVEL 1.[3] Recent data confirmed the benefit of moderate TH in patients with coma who had been resuscitated from cardiac arrest with nonshockable rhythm. The 2015 American Heart Association guideline recommends that comatose adult survivors of cardiac arrest undergo TH between 32°C and 36°C LEVEL 1[4] for shockable rhythms with out-of-hospital cardiac arrest, nonshockable rhythms, and in-hospital cardiac arrest LEVEL 1.[4] A TH is neuroprotective in many ways (see **Table 38.1**). The hypothermia protocol is complex (**Table 38.2**) and requires close monitoring for shivering via the Bedside Shivering Assessment Scale (**Table 38.3**). Sometimes, EEG can detect microshivering that is not palpable on the neck or thorax. Shivering must be treated aggressively, as it increases metabolic demand, raises the patient's core temperature, causes tachycardia, and increases ICP.

TABLE 38.2 Hypothermia Checklist

Contraindications
Absolute contraindications:
• Refractory bleeding at a noncompressible site or uncontrollable bleeding
• Severe and recurrent symptomatic bradycardia requiring pacing or continuous medial therapy
Relative contraindications (consider cooling to 36°C instead of 33°C):
• Acute multisystem organ failure due to prolonged arrest
• Hemodynamic instability requiring more than two vasopressors and/or recurrent cardiac arrests
• Concurrent meningitis
• Severe systemic infection and/or sepsis
• Significant trauma with high risk of internal bleeding
• Severe baseline neurologic or medical disorders
• Pregnancy or postpartum patient
• Head trauma with intracranial bleeding
Induction of Hypothermia
• Immediate initiation of cooling with ice packs, infusion of cold saline, and cooling blanket (protecting the skin from direct contact)
• Use of one of the following methods: superficial cooling pads or intravascular temperature modulation devices
• Administration of one-time paralytic dose for expediting cooling
• Central temperature monitoring with bladder or esophageal probe
• Maintain temperature for 24 h after initiation of hypothermia.

Shivering
• cEEG to detect microshivering
• Goal Bedside Shivering Assessment Scale ≤1
• Acetaminophen 650 every 4 h standing
• Buspar 30 mg orally every 8 h standing
• Meperidine 25 mg IV every 6 h as needed shivering
• Bair hugger set at 43°C for skin counterwarming
• If shivering refractory, can start Mg drip at 0.5-1 g/h with goal Mg level 3-4 mEq/L
• If shivering still refractory, can add fentanyl, propofol, or dexmedetomidine drips
• If shivering remains refractory to sedation, start neuromuscular blockade (must be on sedation) with vecuronium 0.1 mg/kg IV every hour or rocuronium or cisatracurium drips.
Seizures and Myoclonus
• Continuous EEG to identify seizures
• Treat seizures aggressively with phenytoin, valproic acid, levetiracetam, or benzodiazepines.
• Noncortical myoclonus (ie, Lance-Adams syndrome) has no effect on outcome but can be treated for comfort with levetiracetam, valproic acid, gabapentin, or benzodiazepines.
Rewarming to Normothermia
• Rewarm at 0.1°C-0.2°C/h to a goal of 38°C.
• Shivering is most common during rewarming and should be treated aggressively.
Other Monitoring
• Electrolytes should be monitored and repleted to a goal of K = 3.0 mEq/L, as overrepletion can result in hyperkalemia during rewarming.
• Platelets should be transfused for goal >20,000 or >50,000 if active bleeding.

Abbreviations: cEEG, continuous electroencephalography; EEG, electroencephalography; IV, intravenous; K, potassium; Mg, magnesium.

TABLE 38.3 Bedside Shivering Assessment Scale

Score	Severity	Location of Shivering
0	None	None detected on palpation of masseter, neck, and chest muscles
1	Mild	Shivering localized to neck and thorax only
2	Moderate	Shivering involves gross movement of the arms and trunk.
3	Severe	Shivering involves gross movement of the arms, legs, and trunk.

OUTCOME

In 2006, the American Academy of Neurology published guidelines for prognostication in comatose survivors of cardiac arrest after an exhaustive review of the literature (Fig. 38.3). Features that nearly guaranteed poor outcome were early clinical (not electrographic) myoclonic status epilepticus, absent N20 responses on SSEPs in the first 72 hours after arrest, absent corneal or pupillary reflexes or extensor or absent motor response to pain at 72 hours, and serum neuron-specific enolase greater than 33 μg/L. Subsequent studies looking at routine use of hypothermia in comatose patients postcardiac arrest have revealed an unacceptably high false-positive rate of almost every feature (see Fig. 38.3). These findings have prompted further studies on prognostic factors that may be valid for use in the posthypothermia era. In 2014, the European Resuscitation Council's advisory statement on outcome prediction recommended delaying neuroprognostication beyond 72 hours if residual effects of sedation or paralysis are suspected (see Table 38.4 for suggested neuroprognostication checklist after cardiac arrest).

Other biomarkers being studied as predictors of clinical outcome include brain-specific markers such as S100-B and microRNAs, inflammatory markers including C-reactive protein and the interleukins, and neurohormonal markers such as copeptin. Serum neurofilament light chain has shown promise as a predictor of poor

FIGURE 38.3 Prognostication algorithm in comatose survivors of cardiac arrest. On the *left* appear false-positive rate (FPR) and sensitivity of each feature in the prehypothermia era, on the *right* in the posthypothermia era. For posthypothermia era, in cases of multiple studies, the data from the study with the largest number of subjects were used. Abbreviations: NSE, neuron-specific enolase; Sens, sensitivity; SSEP, somatosensory-evoked potential. [a]Major confounders at the time of examination include hypothermia, sedatives/hypnotics, and paralytics. (Adapted from Wijdicks EF, Hijdra A, Young GB, et al. Practice parameter: prediction of outcome in comatose survivors after cardiopulmonary resuscitation [an evidence-based review]: report of the Quality Standards Subcommittee of the American Academy of Neurology. *Neurology*. 2006;67:203-210.)

TABLE 38.4 Recommended Postcardiac Arrest Prognostication Checklist After Therapeutic Hypothermia

First 24 h:
- ☐ Neurologic exam with brainstem reflexes and best motor response
- ☐ NSE daily on days 1-3
- ☐ Noncontrast head CT
- ☐ Connect to continuous EEG and assess reactivity and seizures.
- ☐ Characterize myoclonus (A. spontaneous, stimulus-induced or stimulus-worsened; B. whole body, segmental [one limb] or multifocal; C. if multifocal, synchronous or nonsynchronous; D. stereotyped or nonstereotyped).
- ☐ Document sedatives and paralytics at onset of myoclonus.

Preferred timing of neurologic prognostication is beyond 72 h of postrewarming AND cessation of sedation

5 d postarrest:
- ☐ Order SSEPs; minimize sedation.
- ☐ MRI brain without contrast days 5-7 postarrest or head CT if MRI not feasible

7 d postarrest:
- ☐ Exclude confounders (2.5 half-lives of sedatives, paralytics, metabolic derangements, etc).
- ☐ Brainstem exam and best motor response
- ☐ Follow-up EEG reports (reactivity, seizures, and background patterns)

Abbreviations: CT, computed tomography; EEG, electroencephalography; MRI, magnetic resonance imaging; NSE, neuron-specific enolase; SSEPs, somatosensory-evoked potentials.

outcome compared to neurologic exam or electrophysiologic assessments with comparable specificity. The role of imaging in prognostication is also being studied. In particular, MRI has been studied in an attempt to quantify extent of cerebral damage on ADC. Ultimately, there may be a combination of biomarker and imaging data that may aid in prognostication when the patient's outcome is otherwise indeterminate based on clinical exam, neuron-specific enolase, and SSEP.

It is important to keep in mind the so-called self-fulfilling prophecy that occurs in clinical practice and is a limitation in many studies on outcome after cardiac arrest. There is always a temptation to prognosticate earlier and earlier due to scarcity of resources, anxious families, and astronomical health care costs. Additionally, results of tests that may not accurately predict outcome in the post-TH era can influence clinician decision making. These tests are studied as predictors of outcome but often directly affect the clinician's decision making and counseling to families—thereby confounding any study of outcome. Moving forward, outcome measures need to be changed from survival to degree of neuropsychosocial impairment in survivors.

Intracerebral Hemorrhage 39

Stephan A. Mayer and Fred Rincon

KEY POINTS

1. Intracerebral hemorrhage (ICH) remains the most devastating and most untreatable form of stroke.
2. The most important modifiable risk factor for ICH is chronic hypertension.
3. Oral anticoagulants are a significant cause of ICH, accounting for approximately 15% of cases.
4. Mainstays of ICH management include emergent blood pressure control, correction of coagulopathy, and treatment of mass effect from cerebral edema.
5. Risk factors for poor outcome after ICH include advanced age, hematoma volume, coma, infratentorial location, and the presence of intraventricular hemorrhage.

INTRODUCTION

Intracerebral hemorrhage (ICH) is defined as the acute spontaneous bleeding into the brain parenchyma (**Fig. 39.1**). Primary ICH results from microscopic small artery degeneration in the brain, caused either by chronic, poorly controlled hypertension (80% of cases), or cerebral amyloid angiopathy (CAA; 20% of cases). Secondary ICH refers to intraparenchymal bleeding from a diagnosable anatomic vascular lesion or coagulopathy (**Table 39.1**).

EPIDEMIOLOGY

The overall incidence of ICH is estimated to be 12 to 15 cases per 100,000 per year. As the least treatable and most devastating form of stroke, ICH is a leading cause of mortality, morbidity, and disability in the United States and worldwide, accounting for 10% to 30% of all stroke hospital admissions. Many ICH patients require long-term health care, and only 20% of patients regain functional independence. About 40% to 80% of ICH patients die within the first 30 days, and half of all deaths occur within the first 48 hours.

RISK FACTORS

Hypertension and older age are the strongest predictors of incident ICH. Studies have shown that noncompliance with antihypertensive medications increases the risk of ICH, and control of blood pressure (BP) has been shown to reduce this risk. Chronic hypertension causes a small-vessel vasculopathy characterized by fragmentation, degeneration, and the eventual rupture of small penetrating vessels within the brain termed *lipohyalinosis*. Commonly affected structures include the basal ganglia and thalamus (50%), lobar regions (33%), and brainstem and cerebellum (17%). On pathologic examination, the pattern of small-vessel damage is characterized by (1) degeneration of medial smooth muscle cells; (2) small miliary aneurysms associated with thrombosis

FIGURE 39.1 Basal ganglia intracerebral hemorrhage with hematoma followed by expansion and intraventricular hemorrhage.

TABLE 39.1 Etiologic Factors for Intracerebral Hemorrhage

Risk Factors for Primary Intracerebral Hemorrhage
Demographic
Age
Black race/ethnicity
Vascular Risk Factors
Chronic hypertension (small-vessel disease)
Alcohol
Smoking
Low low-density lipoprotein cholesterol
Vascular Pathology
Amyloid angiopathy (including hereditary forms)
Risk Factors for Secondary Intracerebral Hemorrhage
Brain Infarction
Hemorrhagic transformation of subacute ischemic lesion
Cerebral venous/sinus thrombosis
Preexisting Vascular Lesions
Cavernous angioma
Arteriovenous malformation
Malignancies
Brain tumor
Cerebral metastasis
Inflammatory
Vasculitis
Endocarditis (mycotic aneurysm)
Hematologic
Coagulopathy
Thrombocytopenia
Iatrogenic
Anticoagulants
Fibrinolysis
Toxic
Cocaine
Amphetamines

and microhemorrhages; (3) accumulation of nonfatty debris; and (4) hyalinization of the intima, preferentially at bifurcation points and distal portions of the vessel. It is unclear why some patients develop deep brain infarcts and others develop hemorrhages, but some have implicated the sudden rupture of microaneurysms, also known as *Charcot-Bouchard microaneurysms*, as the basis for ICH. Other nonmodifiable risk factors for ICH include male gender and African American or Japanese race/ethnicity.

Because cholesterol has a key role in the structural formation of cell membranes, low-density lipoprotein cholesterol levels have been implicated as a risk factor for primary ICH, although there is controversy regarding this association, as the results from observational studies and prospective randomized trials of cholesterol reduction have yielded conflicting results.

Heavy alcohol intake has been implicated as a risk factor for ICH in several studies. In theory, alcohol may affect platelet

FIGURE 39.2 Gradient echo magnetic resonance imaging sequence showing multiple chronic cortical microbleeds, diagnostic of amyloid angiopathy.

function and coagulation physiology and enhance vascular fragility.

The CAA is an important risk factor for ICH in the elderly (Fig. 39.2). The CAA is characterized by the deposition of β-amyloid protein in small- to medium-sized blood vessels of the brain and leptomeninges, which may undergo fibrinoid necrosis. It can occur as a sporadic disorder, in association with Alzheimer disease, or with certain familial syndromes (apolipoprotein E2 and E4 allele). Traditionally, CAA has generally been diagnosed by postmortem examination. In certain circumstances, CAA can be ascertained in life by examination of a drained hematoma and/or brain biopsy. The Boston CAA criteria (Table 39.2) is a validated criterion that uses both clinical and radiologic variables for the diagnosis of CAA.

Brain tumors, use of sympathomimetic drugs, coagulopathies, cavernomas, and arteriovenous malformations can also cause brain hemorrhages. Further differential diagnoses of underlying pathologies are summarized in Table 39.1. Although treatment with anticoagulants or fibrinolytic agents entails a higher risk of hemorrhage with increasing doses, the role of aspirin intake in this context is controversial. The detection of microbleeds in gradient echo magnetic resonance imaging (MRI) implies that aspirin is a risk factor for hemorrhage in patients on anticoagulant therapy; MRI evidence of microbleeds should prompt reconsideration of the indications for anticoagulation.

PATHOBIOLOGY

Abrupt arterial rupture leads to rapid accumulation of blood within the brain parenchyma and increase in local tissue pressure followed by the abrupt onset of shearing forces and physical destruction. In addition to the relative mass effect, the hematoma itself induces three early pathophysiologic changes in the surrounding brain tissue: (1) neuronal and glial cell death

TABLE 39.2 Boston Criteria for Diagnosis of Cerebral Amyloid Angiopathy (CAA)-Related Hemorrhage

1. Definite CAA
A. Full postmortem examination demonstrating
i. Lobar, cortical, or corticobasal hemorrhage
ii. Severe CAA with vasculopathy
iii. Absence of other diagnostic lesion
2. Probable CAA with supporting pathology
B. Clinical data and pathologic tissue (evacuated hematoma or cortical biopsy) demonstrating
i. Lobar, cortical, or corticosubcortical hemorrhage
ii. Some degree of CAA in specimen
iii. Absence of other diagnostic lesion
3. Probable CAA
C. Clinical data and MRI or CT demonstrating
i. Multiple hemorrhages restricted to lobar, cortical, or corticosubcortical regions (cerebellar hemorrhage allowed)
ii. Age ≥55 years
iii. Absence of other cause of hemorrhage
4. Possible CAA
D. Clinical data and MRI or CT demonstrating
i. Single lobar, cortical, or corticosubcortical hemorrhage
ii. Age ≥55 years
iii. Absence of other cause of hemorrhage

Abbreviations: CT, computed tomography; MRI, magnetic resonance imaging.

due to apoptosis and inflammation, (2) vasogenic edema, and (3) breakdown of the blood-brain barrier.

Hematoma expansion is an important cause of early neurologic deterioration, and ICH volume is a powerful predictor of outcome after primary ICH. An expanding hematoma may result from persistent bleeding and/or rebleeding from a single arteriolar rupture. Some studies have reported evidence of ICH growth from bleeding into an ischemic penumbra zone surrounding the hematoma, but studies have not confirmed the existence of ischemia in the hypoperfused area in the periphery of the hematoma. Because ischemia does not explain the changes and degree of neurologic dysfunction that occurs after the hemorrhage, neurotoxic and inflammatory mechanisms have more recently been implicated in the pathogenesis of perihemorrhagic tissue damage.

Perihematomal edema may be produced by local and systemic inflammatory mediators that enhance tissue damage either directly or indirectly by the activation of leukocytes, generation of prostaglandins and leukotrienes, and activation of the complement. Intracerebral blood is in part directly responsible for the formation of local edema after ICH.

CLINICAL MANIFESTATIONS

Because most spontaneous hemorrhages arise from tiny vessels, the accumulation of a hematoma takes time and explains the smooth onset of the clinical syndrome over minutes or hours. The progressive course, frequent vomiting, and headache are major points that help to differentiate hemorrhage from infarction.

The *putamen* is the site most frequently affected. When the expanding hematoma involves the adjacent internal capsule, there is a contralateral hemiparesis, usually with hemianesthesia and hemianopia and, in large hematomas, aphasia or impaired awareness of the disorder. However, small self-limiting hematomas close to the capsular region may occasionally mimic lacunar syndromes featuring pure motor or sensory deficits. When the hemorrhage arises in the *thalamus*, hemianesthesia precedes the hemiparesis. Once contralateral motor, sensory, and visual field signs are established, the main points that distinguish the two sites are (1) conjugate horizontal ocular deviation in putaminal hemorrhage and (2) impaired upward gaze in thalamic hemorrhage. *Pontine* hemorrhage usually plunges the patient into coma with quadriparesis and grossly dysconjugate ocular motility disorders, although small hemorrhages may mimic syndromes of infarction. Primary spontaneous hemorrhages within the *mesencephalon* or the *medulla* remain objects of debate and are rare curiosities. When they occur, the anatomic involvement is usually secondary to hemorrhage originating in neighboring diencephalic, cerebellar, or pontine regions. In the *cerebral lobes*, there is an as-yet-unexplained predilection for hemorrhages to occur within the posterior two-thirds of the brain. When they affect one or more cerebral lobes, the syndrome is difficult to distinguish, clinically, from infarction because progressive evolution and vomiting are much less frequent in infarction; also, lobar white matter hematomas often result from arteriovenous malformations, amyloid angiopathy, tumors, or other causes that only uncommonly affect the basal ganglia, thalamus, and pons.

Cerebellar hemorrhage warrants separate description because the mode of onset differs from that of cerebral hemorrhage and because it often necessitates surgical evacuation. The syndrome usually begins abruptly with vomiting and severe ataxia (which usually prevents standing and walking); it is occasionally accompanied by dysarthria, adjacent cranial nerve (mostly sixth and seventh) affection, and paralysis of conjugate lateral gaze to one side, findings that may mislead clinicians into thinking the disease is primarily in the brainstem. However, a cerebellar origin is suggested by the lack of changes in the level of consciousness and lack of focal weakness or sensory loss.

Enlargement of the mass does not change the clinical picture until there is enough brainstem compression to precipitate coma, at which point it is too late for surgical evacuation of the hemorrhage to reverse the disorder. This small margin of time between an alert state and an irreversible coma makes it imperative to consider the diagnosis in all patients with this clinical syndrome and is a reason to have patients who present in the emergency room with vomiting of undetermined origin attempt to stand and walk.

DIAGNOSIS

Nonenhanced computed tomography (CT) scan of the brain is the method of choice to evaluate the presence of ICH (see Fig. 39.1). The CT scan evaluates the size and location of the hematoma, extension into the ventricular system, degree of surrounding edema, and anatomic disruption. Hematoma volume, a powerful predictor of 30-day mortality, can be easily calculated from CT scan images by use of the ABC / 2 method, which involves multiplying the diameter of the hematoma in three dimensions and dividing by 2 (Fig. 39.3). The CT angiography may reveal secondary ICH due to an aneurysm or arteriovenous malformation, or active contrast extravasation into the clot ("spot sign"), which implies an increased risk of early hematoma growth when identified soon after the onset of symptoms. The MRI techniques such as gradient echo are highly sensitive for the diagnosis of ICH as well (see Fig. 39.2). The MRI in patients with atypical ICH patterns on CT may disclose a cause of secondary ICH (ie, tumor, arteriovenous malformation, or hemorrhagic infarction up to 20% of cases). Conventional diagnostic cerebral angiography should be reserved for patients in whom secondary causes of ICH are suspected (see Table 39.1). Findings on CT

FIGURE 39.3 Intracerebral hemorrhage volume measurement. *A*, largest hemorrhage axial diameter; *B*, largest axial diameter perpendicular to A on same slice; *C*, vertical hemorrhage diameter (number of slices with hemorrhage multiplied by slice thickness). For this example, ABC / 2 = (4.4 cm × 3.1 cm × 3.5 cm) / 2 = 23.9 cm³. (From Beslow LA, Ichord RN, Kasner SE, et al. ABC/XYZ estimates intracerebral hemorrhage volume as a percent of total brain volume in children. *Stroke*. 2010;41[4]:691-694, with permission.)

scan or MRI that should prompt angiographic study include the presence of subarachnoid hemorrhage, intraventricular hemorrhage (IVH), underlying calcification, or lobar hemorrhage in nonhypertensive younger patients. Diagnostic catheter angiography should be strongly considered in all patients with primary IVH and younger nonhypertensive patients with lobar ICH.

MEDICAL MANAGEMENT

Prehospital care of ICH follows similar guidelines as for other types of stroke, where the objective is to provide rapid access to medical facilities capable of dealing with stroke patients. The increasing use of mobile stroke units will increase the diagnosis of ICH during the prehospital stage. The BP control, reversal of anticoagulation, and initiation of seizure prophylaxis may start before admission to the emergency department (ED). Clinical trials are planned to evaluate hemostatic therapies such as recombinant factor VIIa (rFVIIa) given within 2 hours of onset for noncoagulopathic ICH in mobile stroke units.

In the ED, ICH patients should be triaged rapidly with CT scans to access stroke units or intensive care units (ICUs). Observation in an ICU or a similar setting is strongly recommended for at least the first 24 hours because the risk of neurologic deterioration is highest during this period and because the majority of patients with brainstem or cerebellar hemorrhage have depressed level of consciousness requiring ventilatory support. A protocolized checklist for care in the ICU is recommended to ensure standardization of best practices (Table 39.3).

TABLE 39.3 Medical Management Checklist for Acute Intracerebral Hemorrhage

Blood pressure	• Maintain systolic arterial pressure between 130 and 150 mm Hg with continuous infusion labetalol, nicardipine, or clevidipine. • If stuporous or comatose, measure ICP and maintain CPP >70 mm Hg.

Reversal of anticoagulation	• For elevated INR: vitamin K 10 mg IV and 4F-PCC
	  • INR 2-<4: 25 U/kg; not to exceed 2,500 units
	  • INR 4-6: 35 U/kg; not to exceed 3,500 units
	  • INR >6: 50 U/kg; not to exceed 5,000 units
	• For dabigatran: idarucizumab 2.5 g IV over 5 min times two doses (total 5 g)
	• For apixaban or rivaroxaban: andexanet alfa IV
	  Low dose = 400 mg bolus + 480 mg over 120 min
	  High dose = 800 mg bolus + 960 mg over 120 min
	  <8 h of ingestion
	  Rivaroxaban <10 mg low dose; >10 mg or unknown high dose
	  Apixaban <5 mg low dose; >5 mg or unknown high dose
	  >8 h of ingestion, use low dose
	• For heparin or LMWH: protamine sulfate 10-50 mg slow IV (1 mg reverses approximately 100 units of heparin)
	• For thrombocytopenia (platelet <100,000/μL) or platelet dysfunction: desmopressin 0.3 μg/kg IV and/or transfuse 1 unit of platelets (single-donor apheresis)

Intracranial hypertension	• Elevate head of bed to 30°. • Analgosedation with propofol, fentanyl, midazolam or dexmedetomidine to a quiet, motionless state • Fever control, acetaminophen, advanced cooling methods • Mannitol 1.0-1.5 g IV and hypertonic saline 23% 30 mL IV over 30 min • Hyperventilate to Pco_2 of 30 mm Hg for <30 min.
Fluids and nutrition	• Normal (0.9%) saline at 1.0 mL/kg/h • Begin enteral feeding via nasoduodenal tube within 24 h.
Seizure prophylaxis	• For coma with intracranial hypertension or acute seizures: fosphenytoin (15-20 mg/kg) followed by 300 mg IV daily or levetiracetam 1,000 mg twice a day for 7 d
Physiologic homeostasis	• Treat fever aggressively. • Insulin drip to maintain glucose 150-180 mg/dL
Deep venous prophylaxis	• Intermittent compression devices upon admission • Start heparin or LMWH 48 h post-ICH.

Abbreviations: CPP, cerebral perfusion pressure; 4F-PCC, four-factor prothrombin complex concentrate containing factors II, VII, IX, and X; ICH, intracerebral hemorrhage; ICP, intracranial pressure; INR, international normalized ratio; IV, intravenously; LMWH, low molecular weight heparin.

Hemostasis and Emergency Reversal of Anticoagulation

The aim of hemostasis is to stop ongoing bleeding and to identify patients for specific reversal strategies who may have received antithrombotic therapies.

Hemostatic Therapy for Noncoagulopathic Intracerebral Hemorrhage

Observational studies indicate that in patients with normal coagulation active bleeding occurs in nearly 40% of patients within the first 2 to 3 hours of symptom onset. The strongest determinant of the risk of continued bleeding is the interval from onset to baseline CT, with shorter intervals implying greater risk. Other features that imply an increased risk of hemorrhage expansion within this early time window include larger baseline hematoma volume, concurrent antiplatelet therapy, greater irregularity of clot contour and density, and presence of contrast extravasation within the hematoma on CT angiography ("spot sign").

Two agents, rFVIIa and tranexamic acid, have been tested in clinical trials in noncoagulopathic ICH patients. Despite the presence of a mild-to-moderate hemostatic effect with these agents (3.8 mL less bleeding with rFVIIa and 1.2 mL less bleeding with tranexamic acid), neither produced significant improvement in outcome at 3 months LEVEL 1.[1,2] More recently, two smaller trials of rFVIIa in ICH patients with a positive spot sign on CT angiography treated as late as 6 hours failed to produce a clinical benefit. To this end, new trials are planned to determine whether rFVIIa can arrest active bleeding and improve outcomes when given within 2 hours of symptom onset.

Reversal Agents for Anticoagulation-Related Intracerebral Hemorrhage

Hemostatic abnormalities in patients with acute ICH should be corrected as rapidly as possible. Patients at risk include those on oral anticoagulants (OACs) for several indications, antiplatelet agents, and congenital or acquired factor or platelet deficiencies. The incidence of ICH related to OACs has increased over the last decade. Vitamin K antagonists are the most commonly prescribed OACs, but newer direct oral anticoagulant (DOAC) agents that inhibit thrombin or factor Xa such as dabigatran, rivaroxaban, and apixaban are increasingly being offered on the basis of superior safety data. As a general measure, activated charcoal 1 g/kg is a treatment option for patients with ICH who have ingested warfarin or a DOAC orally within the last 2 hours.

Warfarin

Patients with ICH receiving warfarin should be reversed immediately with a four-factor prothrombin complex concentrate at a dose of 25 to 50 U/kg depending on the baseline international normalized ratio (INR) (see **Table 39.3**) and vitamin K 10 mg intravenously LEVEL 1.[3,4] Four-factor prothrombin complex concentrates contain the vitamin K–dependent coagulation factors II, VII, IX, and X; normalize the INR more rapidly than fresh frozen plasma; and can be given in much smaller volumes much more rapidly. The rates of hematoma expansion and death are significantly lower in anticoagulated ICH patients achieving correction of INR to <1.3 and systolic blood pressure (SBP) to <160 mm Hg within 4 hours of hospital admission. Treatment should never be delayed in order to check coagulation tests when a patient has acute ICH and a stated history of OAC use.

Dabigatran

For the newer DOACs, specific reversal agents are now U.S. Food and Drug Administration approved in the United States. For ICH related to the direct thrombin inhibitor dabigatran, the monoclonal antibody idarucizumab should be administered intravenously at a dose of 5 g divided into two doses (see **Table 39.3**) LEVEL 1.[5]

Factor Xa Inhibitors

For rivaroxaban, apixaban, edoxaban, and other factor Xa inhibitors, andexanet alfa is an inactive form of factor Xa designed to temporarily bind with high affinity to circulating factor Xa inhibitors in a 1:1 ratio, inhibiting their action. Treatment should be given immediately and dosing depends on the dose of the agent (see **Table 39.3**) LEVEL 1.[6]

Unfractionated and Low Molecular Weight Heparin

Patients with ICH who have been anticoagulated with unfractionated or low molecular weight heparin should be reversed with protamine sulfate. As a general rule, 1 mg of protamine should be given for each 100 mg of unfractionated heparin or 100 units of low molecular weight heparin received within the past 2 hours (see **Table 39.3**).

Antiplatelet Agents

The ICH patients with any form of platelet dysfunction, including renal disease, exposure to antiplatelet agents, or an acquired or hereditary platelet disorder (eg, mechanical circulatory support or von Willebrand disease) can be treated with a single dose of desmopressin 0.3 μg/kg intravenously. It is reasonable to transfuse platelets (6 units of pooled whole blood or 1 unit of single-donor apheresis platelets) to ICH patients who are thrombocytopenic (<50,000/μL). One recent trial reported that platelet transfusions are not helpful, and possibly harmful, in ICH patients on antiplatelet agents LEVEL 1.[7]

Blood Pressure Control

Acute hypertension is common in stroke patients upon arrival to the ED. Acute ICH often leads to extreme arterial hypertension, which has been associated with hematoma expansion, neurologic deterioration, and poor outcome. Excessive reduction in BP after ICH in the setting of impaired autoregulation can theoretically result in exacerbation of ischemic injury, whereas lack of BP control can theoretically exacerbate early hematoma growth and cerebral edema. Single-center studies and a systematic review have reported an increased risk of deterioration, death, or dependency with extremely high or low admission BP after ICH.

Blood Pressure Targets

Two phase 3 clinical trials, INTERACT-2 and ATACH-2, compared standard permissive management (goal SBP <180 mm Hg vs more aggressive BP reduction goal SBP <140 mm Hg). In INTERACT-2, lowering the SBP to <140 mm Hg within 6 hours of onset was not associated with improved functional outcome when the modified Rankin scale was analyzed in a dichotomized fashion as the primary endpoint LEVEL 1.[8] However, when outcome was studied using shift analysis, which measures differences across the entire range of outcomes, a slightly more favorable result was achieved with the <140 mm Hg target. However, this effect was not confirmed in the ATACH-2 study, which was stopped prematurely for futility after an interim analysis of 1,000 patients LEVEL 1.[9] Moreover, ATACH-2 demonstrated

that lowering of SBP <140 mm Hg was associated with higher proportion in serious adverse events, especially renal complications, particularly if SBP fell below 120 mm Hg. Neither trial demonstrated a substantial effect on hematoma expansion. In summary, it appears that the intensive SBP lowering to a range no lower than 130 to 150 mm Hg after ICH is reasonably safe and might be associated with a slight benefit if overshoot is avoided.

Once in the ICU, current American Heart Association guidelines suggest that intracranial pressure (ICP) monitoring should be used in patients with large hematomas and depressed level of consciousness to ensure that cerebral perfusion pressure (CPP) is maintained above 60 mm Hg. A more recent study of 18 comatose ICH patients using brain multimodality monitoring showed that CPP levels less than 80 mm Hg were associated with an increased risk of critical brain tissue hypoxia, which was in turn associated with increased mortality.

Antihypertensive Agents

Given the need to precisely control BP levels in the setting of impaired autoregulation, use of fast-acting continuous infusion agents with intra-arterial monitoring is recommended. Preferred agents are β-blockers (intravenous labetalol) and calcium channel blockers (nicardipine and clevidipine) (Table 39.4). Use of nitroprusside has drawbacks because this agent is associated with higher rate of medical complications and may exacerbate cerebral edema and ICP. Clevidipine, an ultrashort-acting, dihydropyridine L-type calcium channel blocker with rapid onset and offset of action, has also recently been approved for the reduction of BP. Comparative studies have demonstrated that clevidipine is as safe and effective as nitroglycerin, sodium nitroprusside, or nicardipine for reducing BP but has greater ability to maintain a given target range. Oral and sublingual agents are not preferred because of the need for immediate and precise BP control. Although no prospective study has addressed the timing of conversion from intravenous to oral antihypertensive management, this process can generally be started between 24 and 72 hours as long as the patient's critical condition has been stabilized.

Cerebral Edema and Intracranial Pressure

Large-volume ICH carries the risk of developing cerebral edema (Chapter 111) and elevated ICP. Brain swelling can progress for many days after the onset of ICH but most often drives neurologic deterioration within the first 72 hours in patients with hemorrhages exceeding 30 mL in volume. The presence of IVH further increases ICP and the risk of mortality. This effect is primarily related to the development of obstructive hydrocephalus and alterations of normal cerebrospinal fluid flow dynamics. Patients with large-volume ICH, intracranial mass effect, and coma may benefit from ICP monitoring, although this intervention has not been proven to benefit outcomes after ICH.

Management of cerebral edema should be guided by measurement of ICP with an external ventricular drain or parenchymal monitor, with efforts directed at maintaining ICP less than 20 mm Hg and CPP greater than 70 mm Hg. Therapy should be directed by an algorithm that includes head elevation, fever control, analgosedation, CPP optimization, bolus osmotherapy, controlled hyperventilation, and, as a last resort, salvage hemicraniectomy in selected younger patients (see Chapter 111 for a detailed protocol).

TABLE 39.4 Parenteral Vasoactive Agents in Neurologic Emergencies: Preferred Antihypertensives (Listed in Order of Preference)[a]

Drug	Mechanism	Dose	Onset	Duration	Adverse Effects and Cautions	Comments
Clevidipine	L-type CCB (dihydropyridine)	1-2 mg/h infusion	2-4 min	5-15 min	Reflex tachycardia, hypertriglyceridemia. Cautions: soybean allergy	Mean interval 4-6 min to target BP
Nicardipine	L-type CCB (dihydropyridine)	5-15 mg/h infusion	5-10 min	30 min to 4 h	Reflex tachycardia, headache, flushing, local phlebitis; caution in AS and LV failure	Fast acting and easy to titrate
Labetalol	α_1, β_1, β_2 antagonist	20-80 mg bolus every 10 min, up to max 300 mg; then 0.5-2 mg/min infusion	5-10 min	3-6 h	Bradycardia, heart block, bronchospasm, orthostatic hypotension, worsened LV failure	ICH patients may be refractory to beta blockade
Hydralazine	Arterial vasodilator	5-40 mg IV bolus every 6 hours	15 min	5-30 min	Reflex tachycardia, drug-induced lupus syndrome	Use as 2nd or 3rd line therapy
Enalaprilat	ACE inhibitor	0.625 mg test dose then 1.25-5 mg every 6 h	15-30 min	6-12 h	Variable response, precipitous fall in BP in high-renin states	Use as 2nd or 3rd line therapy
Nitroprusside[b]	Nitrovasodilator (arterial and venous)	0.25-10 μg/kg/min infusion	Immediate	1-4 min	Thiocyanate and cyanide intoxication, unreliable response with excessive BP reduction, ICP elevation	Should not be used as 1st line therapy

Abbreviations: ACE, angiotensin-converting enzyme; AS, aortic stenosis; BP, blood pressure; CCB, calcium channel blocker; COPD, chronic obstructive pulmonary disease; HTN, hypertension; ICP, intracranial pressure; LV, left ventricle; MI, myocardial infarction.

[a]Data from Rose JC, Mayer SA. Optimizing blood pressure in neurological emergencies. *Neurocrit Care*. 2004;1(3):287-299.

[b]Nitroprusside is becoming less favored for use in neurologic emergencies (see text).

Because controlled ventilation, sedation, and CPP targets are usually maintained in the background over the long term, bolus osmotherapy with either 1.0 to 1.5 g/kg of 20% mannitol or 0.5 to 2.0 mL/kg of 23.4% hypertonic saline are the main weapons at the clinician's disposal for actively herniation or ICP. The effectiveness of 23.4% saline solution over 10% saline and mannitol during imminent transtentorial herniation has been demonstrated in a canine model of ICH, but for the most part, both solutions can be considered equivalent, with a peak ICP-lowering effect at 30 minutes. Apart from a negative trial of glycerol given within 48 hours of ICH onset, no prospective randomized control trials have compared the effectiveness of the different osmotic agents available for the management of increased ICP in ICH. Effectiveness of hyperosmolar therapy for control of ICP depends on rapid institution of therapy and achieving higher differences in baseline osmolarity. Corticosteroids such as dexamethasone do not improve the outcome of ICH and are not indicated for the treatment of cerebral edema associated with ICH LEVEL 2.[10]

Seizures

Twelve percent of ICH patients experience convulsive seizures during their hospitalization; the risk is increased with lobar location. Seizure activity in ICH patients should aggressively be diagnosed and treated. Patients with ICH may benefit from prophylactic antiepileptic therapy (antiepileptic drugs [AEDs]), but no randomized trial has addressed the use of AEDs in the setting of ICH so current guidelines do not endorse the use of AEDs for ICH patients without seizures. Continuous electroencephalographic monitoring is recommended in all comatose patients in order to detect convulsive seizures or status epilepticus. Even with anticonvulsant therapy, continuous electroencephalographic monitoring reveals electrographic seizure activity in 20% of comatose patients. It is unclear whether midazolam infusion or other aggressive measures to eliminate these seizures can improve outcome. If seizures have not occurred, anticonvulsants should be discontinued at discharge because they can hamper neurologic recovery during rehabilitation.

Medical Support

For patients requiring ventilatory support, maintain normoxia and normocapnia, avoid routine hyperoxygenation, and prevent ventilator-associated infections. Additional measures in the stroke unit or ICU include evaluation and assessment of speech and swallowing for nutritional support, maintenance of normoglycemia (goal <180 mg/dL), gastrointestinal prophylaxis for intubated patients, and deep venous thrombosis prophylaxis, which can be safely started 48 hours after ICH onset. Early enteral feeding should be initiated via a nasoduodenal feeding tube within inpatients who lack the capacity to swallow to combat malnutrition and muscle wasting. Though the relationship between fever, cerebral edema and poor outcome after ICH has been established in observational studies, no prospective data is currently available to evaluate the impact of active fever prophylaxis. Trials evaluating this treatment strategy are underway. Until further evidence becomes available, fever should be actively treated with antipyretics and advanced cooling methods if needed.

SURGICAL MANAGEMENT

The most urgent treatment consideration for ICH is often whether to proceed emergently with surgical evacuation or external ventricular drain placement. Owing to the irreversible nature of secondary brain injury related to herniation and ICP, results are always better when definitive measures to reverse these processes are performed as soon as possible. Delayed surgical intervention triggered by clinical deterioration must always be tempered by realization that an earlier procedure would have been the better plan.

Ventricular Drainage

An external ventricular drain is indicated in all stuporous or comatose patients with IVH and ventricular enlargement in whom aggressive support is indicated. This lifesaving procedure, which can be performed at the bedside, decompresses the intracranial vault and arrests the process of downward brainstem herniation by allowing drainage of bloody cerebrospinal fluid into a drainage receptacle. Connecting the drainage system to a pressure transducer also allows measurement of ICP and monitoring of CPP.

Intraventricular thrombolysis with tissue plasminogen activator (1 mg every 8 h over a maximum of 4 d) has been given to promote clot lysis and possibly improve neurologic outcome by reducing obstructive hydrocephalus and hemorrhage-related neurotoxicity. The CLEAR-III study found that at 6 months, this treatment reduces mortality but increases the proportion of survivors dependent with poor functional outcome, resulting in no net benefit in terms of survival with good outcome LEVEL 2.[11] For this reason, intraventricular thrombolysis remains a therapeutic option but is not considered standard of care.

Craniotomy

Apart from cases suffering cerebellar hemorrhage, any decision on whether, how, and when to intervene neurosurgically after ICH is subject to intense debate and awaits further data from ongoing prospective trials. To date, all clinical trials have failed to show a superiority of hematoma evacuation over medical therapy for supratentorial ICH in both patients with hematoma >2 cm in diameter and Glasgow Coma Scale score ≥5 (STICH-I) or in conscious patients with superficial lobar ICH 10 to 100 mL without IVH (STICH-II) LEVEL 2.[12,13] However, these trials did not enroll patients if the investigator felt that emergency surgery was clearly a lifesaving intervention, leading to inclusion bias. Many experts feel that urgent craniotomy can improve the outcome of younger patients with large lobar hemorrhages and a deteriorating course due to mass effect (Fig. 39.4).

In contrast to supratentorial ICH, it is widely accepted that patients with cerebellar hemorrhages exceeding 3 cm in diameter benefit from emergent surgical evacuation. Abrupt and dramatic deterioration to coma can occur within the first 24 hours of onset in these patients. For this reason, it is generally unwise to defer surgery in these patients until further clinical deterioration occurs.

Minimally Invasive Surgery

As emergent craniotomy has been unable to improve neurologic outcome after ICH, the role of other surgical techniques such as minimally invasive surgery has garnered interest over the last decade, and good anecdotal results have been reported (Fig. 39.5).

FIGURE 39.4 Lifesaving hemicraniectomy in a patient with lobar intracerebral hemorrhage considered otherwise lethal.

The advantages of minimally invasive surgery over conventional craniotomy include reduced operative time, the possibility of performance under local anesthesia, and reduced surgical trauma to the brain. However, in the recent MISTIE III trial, catheter-directed clot aspiration assisted with thrombolysis (tissue plasminogen activator 1 mg every 8 h) failed to improve functional outcomes LEVEL 2.[14] Further trials evaluating a variety of endoscopic suction devices are planned or underway.

SECONDARY PREVENTION

The risk of recurrent ICH is 2% per year in patients with chronic hypertension, and in those patients with diastolic BP higher than 90 mm Hg, the rate of recurrence is as high as 10% per year. The BP reduction significantly decreases the risk of ICH and other forms of stroke and is unequivocally the most effective method for primary and secondary prevention of ICH. In the Perindopril Protection Against Recurrent Stroke Study trial, a BP regimen of perindopril, an angiotensin-converting enzyme inhibitor, was found to be more effective than placebo for preventing recurrent stroke among both hypertensive and nonhypertensive individuals following incident stroke or transient ischemic attack LEVEL 2.[15]

Prior studies have demonstrated that all survivors of lobar ICH and some patients with deep hemispheric ICH who have a history of atrial fibrillation should not be offered long-term anticoagulation therapy due to the high risk of recurrent hemorrhage. Conversely, patients with a high risk of thromboembolic events and low recurrent risk of ICH may benefit from long-term anticoagulation therapy. Cerebral microbleeds, a phenotype of small vessel

FIGURE 39.5 Schematic representation of the Stereotactic Intracerebral Hemorrhage Underwater Blood Aspiration technique for minimally invasive endoscopic intracerebral hemorrhage evacuation. **A:** The endoscope sheath is inserted 1.5 cm from the distal wall of the hematoma under stereotactic guidance. **B:** Blood is aspirated until the brain closes in around the end of the sheath at which point it is retracted 1 to 2 cm. **C:** When the sheath retracts to the proximal wall of the hematoma cavity, saline is infused through the sheath, inflating the hematoma cavity. **D:** After evacuation, the sheath is removed, and burr hole ultrasound followed by DynaCT are performed to confirm adequate removal. (From Kellner CP, Chartrain AG, Nistal DA, et al. The Stereotactic Intracerebral Hemorrhage Underwater Blood Aspiration [SCUBA] technique for minimally invasive endoscopic intracerebral hemorrhage evacuation. *J NeuroIntervent Surg*. 2018;10[8]:771-776, with permission.)

disease that can be detected on susceptibility weighted or gradient echo MRI, are biomarkers that imply an even particularly high risk of recurrent ICH. This form of imaging may be useful in evaluating the risk and benefits of long-term anticoagulation in ICH survivors with atrial fibrillation or venous thromboembolic disease.

PROGNOSIS

The mortality of ICH is 35% to 50% at 30 days and 47% at 1 year. Factors that consistently predict mortality or adverse outcomes in ICH have been studied extensively. Independent predictors for 30-day and 1-year mortality include Glasgow Coma Scale and/or depressed level of consciousness, age, ICH volume, presence of IVH, and infratentorial origin. A simple clinical grading scale, the *ICH Score* (**Table 39.5**), permits calculation of mortality, allowing use of uniform terms and enhancing communication between physicians. The mortality rates for scores of 0, 1, 2, 3, 4, and 5 are 0%, 13%, 26%, 72%, 97%, and 100%, respectively. Additional factors associated with high mortality after ICH include the presence of subarachnoid hemorrhage, wide pulse pressure, history of coronary artery disease, and hyperthermia. Factors associated with good outcomes include a low National Institutes of Health Stroke Scale score and low temperature on admission.

Except in the most severe cases, caution is warranted when communicating a hopeless prognosis before aggressive efforts have been made to resuscitate victims of ICH. It has become increasingly evident that physicians tend to underestimate the chances of a good outcome and that many poor outcomes result from self-fulfilling prophesies of doom. Mortality after ICH is reduced in patients cared for in a specialty neurologic ICU. This is presumably the result of adherence to best medical practices, early transition to rehabilitation, and being cared for by a team or health care professionals who take an active interest in promoting survival and recovery.

TABLE 39.5 Determination of the Intracerebral Hemorrhage (ICH) Score[a]

Component	Score Points
Glasgow Coma Scale Score	
3-4	2
5-12	1
13-15	0
ICH Volume (cm^3)	
≥30	1
<30	0
Intraventricular Hemorrhage	
Yes	1
No	0
Infratentorial ICH	
Yes	1
No	0
Age (y)	
≥80	1
<80	0

Subarachnoid Hemorrhage 40

Stephan A. Mayer, Gary L. Bernardini, and Robert A. Solomon

KEY POINTS

1. The cardinal symptom of subarachnoid hemorrhage (SAH) is "the worst headache of my life."
2. In 85% of cases, SAH is caused by rupture of an identifiable saccular "berry" aneurysm.
3. Left untreated, the risk of aneurysm rebleeding is 20% after 2 weeks and 30% after 1 month.
4. Endovascular coiling has been shown to be safer than open surgical clipping in good-grade patients with anterior circulation aneurysms.
5. Approximately 70% of SAH patients develop delayed arterial vasospasm, resulting in delayed cerebral ischemia in 20% to 30%.
6. The calcium channel blocker nimodipine reduces the risk of delayed cerebral ischemia from vasospasm.
7. Hemodynamic augmentation and intra-arterial vasodilators are mainstays of rescue therapy for symptomatic vasospasm.

INTRODUCTION

Subarachnoid hemorrhage (SAH) accounts for 5% of all strokes; it affects nearly 30,000 people each year in the United States, with an annual incidence of 1 per 10,000. Saccular (or berry) aneurysms at the base of the brain cause 80% of all cases of SAH. Nonaneurysmal causes of SAH are listed in **Table 40.1**.

TABLE 40.1 Nonaneurysmal Causes of Subarachnoid Hemorrhage (SAH)

• Trauma
• Idiopathic perimesencephalic SAH
• Arteriovenous malformation
• Intracranial arterial dissection
• Cocaine and amphetamine use
• Mycotic aneurysm
• Pituitary apoplexy
• Moyamoya disease
• Central nervous system vasculitis
• Sickle cell disease
• Coagulation disorders
• Primary or metastatic neoplasm

SAH most frequently occurs between ages 40 and 60 years, and women are affected more often than men.

SAH due to the rupture of an intracranial aneurysm is a devastating event; approximately 12% of patients die before receiving medical attention, and another 20% die after admission to the hospital. Of the two-thirds of patients who survive, approximately one-half remain permanently disabled, primarily due to neurocognitive deficits and depression. Advances in neurosurgery and intensive care, including an emphasis on early aneurysm clipping and aggressive therapy for vasospasm, have led to improved survival over the last three decades, with a reduction in overall case fatality from approximately 50% to 20% in high-volume centers.

PATHOLOGY AND EPIDEMIOLOGY OF INTRACRANIAL ANEURYSMS

Saccular aneurysms most often occur at the circle of Willis or its major branches, especially at bifurcations. They arise where the arterial elastic lamina and tunica media are defective and tend to enlarge with age. The typical aneurysm wall is composed only of intima and adventitia and can become paper thin. Many aneurysms, particularly those that rupture, are irregular and multilobulated, and larger aneurysms may be partially or completely filled with an organized clot, which occasionally is calcified. The point of rupture is usually through the dome of the aneurysm.

Eighty-five percent to 90% of intracranial aneurysms are located in the anterior circulation, with the three most common sites being the anterior communicating artery complex (approximately 40%), the junction of the posterior communicating and internal carotid artery (approximately 30%), and the middle cerebral artery at the first major branch point in the sylvian fissure (approximately 20%). Posterior circulation aneurysms most often occur at the apex of the basilar artery or at the junction of the vertebral and posteroinferior cerebellar artery. Saccular aneurysms of the distal cerebral arterial tree are rare. Nearly 20% of patients have two or more aneurysms; many of these are "mirror" aneurysms on the same vessel but on the contralateral side.

Intracranial aneurysms are uncommon in children but occur with a frequency of 2% in adults, suggesting that approximately 2 to 3 million Americans have an aneurysm. However, more than 90% of these are small (<10 mm) and remain asymptomatic throughout life. The annual risk of rupture of an asymptomatic intracranial aneurysm is approximately 0.7%. Important risk factors for the initial rupture of an aneurysm include increasing size, prior SAH from a separate aneurysm, and basilar apex and posterior communicating artery location (**Table 40.2**). The most powerful of these risk factors is size: For example, internal carotid artery aneurysms less than 7 mm in diameter bleed at a

TABLE 40.2 Five-Year Cumulative Hemorrhage Rates of Unruptured Aneurysms According to Size and Location[a]

	<7 mm				
	No Prior SAH	Prior SAH[b]	8-12 mm	13-25 mm	≥25 mm
Cavernous carotid artery (N = 210)	0	0	0	3.0%	6.4%
ACA, MCA, ICA (not intracavernous) (N = 1,037)	0	1.5%	2.6%	14.5%	40%
Posterior circulation or P-comm (N = 445)	2.5%	3.4%	14.5%	18.4%	50%

Abbreviations: ACA, anterior communicating or anterior cerebral artery; ICA, internal carotid artery; MCA, middle cerebral artery; P-comm, posterior communicating artery; SAH, subarachnoid hemorrhage.

[b]Refers to prior subarachnoid hemorrhage from a separate intracranial aneurysm.

rate of approximately 0.1% per year, compared to an annual rate of 8% for those greater than 25 mm in size. Other risk factors for aneurysm rupture in approximate order of importance include cigarette smoking, aneurysm-related headache or cranial nerve compression, heavy alcohol use, a family history of SAH, female sex (especially when postmenopausal), multiple aneurysms, hypertension, and exposure to cocaine or other sympathomimetic agents. In deciding whether to treat an unruptured intracranial aneurysm, the risks associated with repair should always be balanced against the patient's estimated lifetime risk of hemorrhage without repair.

The prevalence of aneurysms increases with age and is higher in patients with atherosclerosis, a family history of intracranial aneurysm, or autosomal dominant polycystic kidney disease. Intracranial aneurysms have also been associated with Ehlers-Danlos syndrome, Marfan syndrome, pseudoxanthoma elasticum, coarctation of the aorta, and sickle cell disease. Screening for unruptured intracranial aneurysms with computed tomography (CT) or magnetic resonance angiography is indicated in patients with polycystic kidney disease and in family members who have two or more first-degree relatives with intracranial aneurysms; testing is positive in 5% to 10% of these individuals.

CLINICAL FEATURES

SAH usually commences with an explosive "thunderclap" headache followed by stiff neck. The pain is often described as "the worst headache of my life." The headache is usually generalized, but focal pain may refer to the site of aneurysmal rupture (eg, periorbital pain related to an ophthalmic artery aneurysm). Commonly associated symptoms include loss of consciousness, nausea and vomiting, back or leg pain, and photophobia. In patients who lose consciousness, tonic posturing may occur and may be difficult to differentiate from a seizure. Although aneurysmal rupture often occurs during periods of exercise or physical stress, SAH can occur at any time, including sleep.

Approximately 20% of patients give a history of suspicious symptoms days or weeks earlier, including headache, stiff neck, nausea and vomiting, syncope, or disturbed vision. These prodromal symptoms are often due to minor leaking of blood from the aneurysm and are therefore referred to as "warning leaks" or "sentinel headaches." Initial misdiagnosis of SAH occurs in approximately 15% of patients, and those with the mildest symptoms are at greatest risk. Approximately 40% of misdiagnosed patients experience subsequent neurologic deterioration due to rebleeding, hydrocephalus, or vasospasm before reaching medical attention, with increased morbidity and mortality.

Stiff neck and the Kernig sign are hallmarks of SAH. However, these signs are not invariably present, and confusion and low back pain are sometimes more prominent than headache. Preretinal or subhyaloid hemorrhages—large, smooth-bordered, and on the retinal surface—occur in up to 25% of patients and are practically pathognomonic of SAH.

The most important determinant of outcome after SAH is the patient's neurologic condition on arrival at the hospital. Alterations in mental status are the most common abnormality; some patients remain alert and lucid; others are confused, delirious, amnestic, lethargic, stuporous, or comatose. The modified Hunt and Hess grading scale serves as a means for risk stratification for SAH based on the first neurologic examination (Table 40.3). Patients classified as grade I or II SAH have a relatively very good prognosis (<5% mortality), grades III and IV carry an intermediate prognosis (10%-15% mortality), and grade V patients have a poor prognosis (50%-70% mortality). Focal neurologic signs occur in a minority of patients but may point to the site of bleeding; hemiparesis or aphasia suggests a middle cerebral artery aneurysm, and paraparesis or abulia suggests an aneurysm of the proximal anterior cerebral artery. These focal signs are sometimes due to a large hematoma, which may require emergency evacuation.

TABLE 40.3 Mortality According to the Hunt-Hess Grading Scale for Aneurysmal Subarachnoid Hemorrhage[a]

		Hospital Mortality (%)	
Grade	Clinical Findings	1968	2012
I	Asymptomatic or mild headache	11	3
II	Moderate to severe headache or oculomotor palsy	26	3
III	Confused, drowsy, or mild focal signs	37	9
IV	Stupor (localizes to pain)	71	24
V	Coma (posturing or no motor response to pain)	100	70
TOTAL		35	20

[a]Data are from 275 patients reported by Hunt and Hess in 1968 and 1,200 patients treated at Columbia University Medical Center between 1996 and 2012.

FIGURE 40.1 Two computed tomography images of subarachnoid hemorrhage (SAH). **A:** Diffuse, thick SAH is seen in the anterior interhemispheric and bilateral sylvian fissures and the quadrigeminal cistern. A left middle cerebral artery aneurysm was identified. **B:** Perimesencephalic SAH; only a small focus of blood in the interpeduncular cistern is identified. No aneurysm was identified.

About 15% of patients with spontaneous nontraumatic SAH have no identifiable aneurysm on angiography. In about half of these cases, CT reveals blood confined to the perimesencephalic cisterns, with the center of bleeding adjacent to the midbrain and pons (Fig. 40.1). Patients with "perimesencephalic" SAH always have normal findings on neurologic examination and a benign clinical course; rebleeding and symptomatic vasospasm or hydrocephalus almost never occur. The source of hemorrhage in these patients is presumably venous. In patients with extensive and diffuse SAH and a negative angiogram, the bleeding source is presumably a "blister" aneurysm.

Symptoms and signs of an unruptured intracranial aneurysm may result from compression of adjacent neural structures or thromboembolism. These aneurysms are often, but not always, large or giant (>25 mm). Aneurysms of the posterior communicating artery frequently compress the oculomotor nerve (almost always affecting the pupil). Aneurysms of the intracavernous segment of the internal carotid artery may damage the third, fourth, fifth, or sixth cranial nerves, and their rupture can lead to formation of a carotid-cavernous fistula. Less often, large aneurysms compress the cortex or brainstem, causing focal neurologic signs or seizures. Thrombosis within the aneurysmal sac occasionally sends emboli to the artery's distal territory, causing transient ischemic attacks or infarction. In the absence of SAH, some patients experience sudden, severe headache without nuchal rigidity, perhaps related to aneurysmal enlargement, thrombosis, or meningeal irritation; these symptoms can clear with aneurysm clipping.

DIAGNOSIS

Computed Tomography

CT should be the first diagnostic study for establishing the diagnosis of SAH because it is readily available and interpretation is straightforward. When SAH is misdiagnosed, the most common error is failure to obtain a CT scan. CT most commonly demonstrates diffuse blood in the basal cisterns (see Fig. 40.1); with more severe hemorrhages, blood extends into the sylvian and interhemispheral fissures, ventricular system, and over the convexities. The distribution of blood can provide important clues regarding the location of the ruptured aneurysm. CT may also demonstrate a focal intraparenchymal or subdural hemorrhage, ventricular enlargement, a large thrombosed aneurysm, or infarction due to vasospasm. The sensitivity of CT for SAH is 90% to 95% within 24 hours, 80% at 3 days, and 50% at 1 week. Accordingly, a normal CT never rules out SAH, and a lumbar puncture should always be performed in patients with suspected SAH and negative CT. Magnetic resonance imaging (MRI) can also be used to make the initial diagnosis of SAH or can be used to detect a completely thrombosed aneurysm if the initial angiogram is negative. The Ottawa SAH Rule (Table. 40.4) includes six clinical features that collectively have 100% sensitivity for CT or lumbar puncture documented SAH among patients presenting with acute headache peaking within 1 hour of onset. If all six features are absent, SAH is effectively ruled out and imaging is not needed.

TABLE 40.4 The Ottowa Subarachnoid Hemorrhage Rule for Acute Headache

Investigation to rule out SAH (CT followed by LP) required if any one of the following are present
- Symptom of neck pain or stiffness
- Age > 40 yr
- Witnessed loss of consciousness
- Onset during exertion
- Thunderclap headache (peak pain instantly)
- Limited neck flexion upon exam

If all of the above are absent, SAH has effectively been ruled out.

Lumbar Puncture

The cerebrospinal fluid (CSF) is usually grossly bloody. SAH can be differentiated from a traumatic tap by a xanthochromic (yellow-tinged) appearance of the supernatant fluid after centrifugation. However, xanthochromia may take up to 12 hours to appear. The CSF pressure is nearly always high and the protein elevated. Initially, the proportion of CSF leukocytes to erythrocytes is that of peripheral blood, with a usual ratio of 1:700; after several days, a reactive pleocytosis and low glucose levels may arise from a sterile chemical meningitis caused by the blood. Red blood cells and xanthochromia disappear in about 2 weeks, unless hemorrhage recurs.

Angiography

Cerebral angiography is the definitive diagnostic procedure for detecting intracranial aneurysms and defining their anatomy (Fig. 40.2). Although the increasing availability and image quality of CT and magnetic resonance angiography has allowed some centers to use these tests to make the initial diagnosis, a four-vessel (bilateral internal carotid and vertebral artery injections) angiogram is mandatory when those tests are negative. Moreover, angiography performed during coiling or after surgical clipping is generally advisable to evaluate the adequacy of aneurysmal repair and to screen for smaller secondary aneurysms that may be missed by CT or magnetic resonance angiography. Vasospasm, local thrombosis, or poor technique can lead to a false-negative angiogram. For this reason, patients with

FIGURE 40.2 Lateral view of a left common carotid angiogram demonstrates a bilobed aneurysm of the left internal carotid artery *(arrow)* at the level of the posterior communicating artery. (Courtesy of Dr. S. Chan.)

a negative angiogram at first should have a follow-up study 1 to 2 weeks later; an aneurysm will be demonstrated in about 5% of these cases. The exception to this rule is found in patients with "perimesencephalic" SAH who usually do not require follow-up angiography.

Laboratory Testing

In addition to routine admission laboratory tests, care should be taken to check a prothrombin time/partial thromboplastin time to diagnose a coagulopathy, an electrocardiogram and serum troponin level to diagnose sympathetically mediated cardiac injury, and a chest X-ray to diagnose neurogenic pulmonary edema or aspiration pneumonitis. Patients with electrocardiogram abnormalities (typically peaked T-waves with QTc segment prolongation) or troponin elevation should have an echocardiogram performed.

COMPLICATIONS OF ANEURYSMAL SUBARACHNOID HEMORRHAGE

Rebleeding

Aneurysmal rebleeding is a dreaded complication of SAH. The risk of rebleeding is highest within the first 24 hours after the initial aneurysmal rupture (4%) and remains elevated (approximately 1%-2% per day) for the next 4 weeks (Fig. 40.3). The cumulative risk of rebleeding in untreated patients is 20% at 2 weeks, 30% at 1 month, and 40% at 6 months. After the first 6 months, the risk of rebleeding is 2% to 4% annually. Poor clinical grade and larger aneurysm size are the strongest risk factors for in-hospital rebleeding. The prognosis of patients who rebleed is poor; approximately 50% die immediately, and another 30% die from subsequent complications. Although rebleeding is often attributed to uncontrolled hypertension, elevated blood pressure has not been convincingly linked to an increased risk of aneurysm rebleeding. Endogenous fibrinolysis of clot around the rupture point of the aneurysm may be a more important causative mechanism.

Vasospasm

Delayed cerebral ischemia (DCI) from vasospasm accounts for a large proportion of morbidity and mortality after SAH. Progressive arterial narrowing develops after SAH in approximately 70% of patients, but delayed ischemic deficits develop in only 20% to 30%. The process begins 3 to 5 days after the hemorrhage, becomes maximal at 5 to 14 days, and gradually resolves over 2 to 4 weeks. Accordingly, deterioration attributable to vasospasm never occurs before the third day after SAH and occurs with peak frequency between 5 and 7 days (see Fig. 40.3). There is a strong relationship between the amount of cisternal blood seen on initial CT and the risk for development of symptomatic ischemia; for uncertain reasons, the presence

FIGURE 40.3 The daily percentage probability for the development of symptomatic vasospasm *(solid line)* or rebleeding *(dashed line)* after subarachnoid hemorrhage. Day 0 denotes day of onset of subarachnoid hemorrhage.

TABLE 40.5 Modified Fisher Computed Tomography Rating Scale for the Prediction of Symptomatic Vasospasm[a]

Grade	Criteria	Percentage of Affected Patients	Frequency of Delayed Cerebral Ischemia	Frequency of Infarction
0	No SAH or IVH	5%	0%	0%
1	Minimal/thin SAH, no biventricular IVH	30%	12%	6%
2	Minimal/thin SAH, *with* biventricular IVH	5%	21%	14 %
3	Thick SAH,[b] no biventricular IVH	43%	19%	12%
4	Thick SAH,[b] *with* biventricular IVH	17%	40%	28%
	All patients	100%	20%	12%

Abbreviations: IVH, intraventricular hemorrhage; SAH, subarachnoid hemorrhage.
[a]From Claassen J, Bernardini GL, Kreiter K, et al. Effect of cisternal and ventricular blood on risk of delayed cerebral ischemia after subarachnoid hemorrhage: the Fisher scale revisited. *Stroke*. 2001;32:2012-2020.
[b]Thick SAH is defined as completely filling at least one cistern or fissure.

of large amounts of blood in the lateral ventricles adds to this risk (Table 40.5). Symptomatic vasospasm usually involves a decrease in level of consciousness, hemiparesis, or both, and the process is usually most severe in the immediate vicinity of the aneurysm. In more severe cases, the symptoms develop earlier after aneurysm rupture, and multiple vascular territories are involved.

Although thick subarachnoid blood is the principal precipitating factor, the precise cause of arterial narrowing after SAH is poorly understood. Vasospasm is not simply due to vascular smooth muscle contraction, and changes in vessel caliber develop slowly over several days. Inflammatory arteriopathic changes are seen in the vessel wall, including subintimal edema and infiltration of leukocytes. The prevailing view is that substances released from the blood clot interact with the vessel wall to cause inflammatory arterial spasm. Putative mediators with intrinsic vasoconstrictive properties include oxyhemoglobin, hydroperoxides and leukotrienes, free radicals, prostaglandins, thromboxane A2, serotonin, endothelin, platelet-derived growth factor, and other inflammatory mediators. Cortical spreading depolarization may further contribute to DCI after SAH by creating prolonged neuronal depolarization in conjunction with a paradoxical reduction in local cerebral blood flow.

Hydrocephalus

Acute symptomatic hydrocephalus occurs in 15% to 20% of patients with SAH and is primarily related to the volume of intraventricular and subarachnoid blood. In mild cases, hydrocephalus causes lethargy, psychomotor slowing, and impaired short-term memory. Additional findings may include limitation of upward gaze, sixth cranial nerve palsies, and lower extremity hyperreflexia. In more severe cases, acute obstructive hydrocephalus leads to elevated intracranial pressure and stupor or coma. Progressive brainstem herniation eventually results from continued CSF production unless a ventricular catheter is inserted.

Delayed hydrocephalus may develop 3 to 21 days after SAH. The clinical syndrome is that of normal pressure hydrocephalus, with failure to fully recover and prominent symptoms of dementia, gait disturbance, and urinary incontinence. The clinical response to ventriculoperitoneal shunting is usually excellent. Overall, 20% of SAH survivors require shunting for chronic hydrocephalus.

Global Cerebral Edema and Early Brain Injury

CT often demonstrates a characteristic form of global brain edema after poor-grade SAH (Fig. 40.4). This finding is most common in patients who experience loss of consciousness at the onset of bleeding, suggesting a transient episode of intracranial circulatory arrest with subsequent reperfusion injury to the brain. Global cerebral edema after SAH has been linked to an increased risk of mortality, disability, and cognitive dysfunction among survivors. MRI performed within 72 hours shows a distinctive pattern of symmetric ischemic injury in 70% of Hunt-Hess grade IV or V patients, most often involving the anterior

FIGURE 40.4 Global edema on the admission computed tomography scan (subarachnoid hemorrhage [SAH] day 0) in a 55-year-old man with a Hunt-Hess grade V SAH from a left anterior communicating artery aneurysm, which was clipped. Note the complete effacement of all convexity sulci and presence of "fingerlike" extensions of white matter lucencies to the cortical surface. A follow-up scan on SAH day 18 showed complete normalization of the CT findings. (From Claassen J, Carhuapoma JR, Kreiter KT, et al. Global cerebral edema after subarachnoid hemorrhage: frequency, predictors, and impact on outcome. *Stroke*. 2002;33:1225-1232.)

cerebral artery territories, a process termed *early brain injury*. The relative contribution of acute ischemia, reperfusion injury, microvascular dysfunction, inflammation, and spreading depolarization in early brain injury remains poorly understood.

Seizures

Clinically obvious tonic-clonic seizures occur in 5% of SAH patients during hospitalization and in another 10% in the first year after discharge. Seizures after SAH are related primarily to focal pathology, including large subarachnoid clots, subdural hematoma, or cerebral infarction. Ictal events at the onset of bleeding do not portend an increased risk of late seizures. With continuous electroencephalographic monitoring, nonconvulsive seizures or status epilepticus can be detected in up to 20% of poor-grade patients and has become increasingly recognized as a cause of otherwise unexplained clinical deterioration after SAH, with ominous implications for prognosis.

Fluid and Electrolyte Disturbances

Hyponatremia and intravascular volume contraction frequently occur after SAH and reflect homeostatic derangements that favor excessive free-water retention and sodium loss. Hyponatremia occurs in 5% to 30% of patients after SAH and is usually related to inappropriate secretion of antidiuretic hormone and free-water retention. This process may be further exacerbated by excessive natriuresis that occurs after SAH ("cerebral salt wasting"), related to elevations of atrial natriuretic factor and the glomerular filtration rate. Whereas hyponatremia after SAH is usually asymptomatic, untreated sodium losses resulting in intravascular volume contraction can increase the risk of DCI in the presence of vasospasm. To minimize the development of hypovolemia and hyponatremia after SAH, patients should be given large volumes of isotonic crystalloid, with restriction of other potential sources of free water.

Neurogenic Cardiac and Pulmonary Disturbances

Severe SAH is typically associated with a surge in catecholamine levels and sympathetic tone, which in turn can lead to neurogenic cardiac dysfunction, neurogenic pulmonary edema, or both (see Chapter 119). Transient electrocardiographic abnormalities occur in 50% to 100% of SAH patients but usually do not produce symptoms. In 5% to 10% of poor-grade patients, however, cardiac enzyme release and a reversible form of neurogenic "stunned myocardium" can occur. Cardiac troponin elevation always occurs, but the extent of these elevations is usually smaller than expected compared to ischemic acute coronary syndromes. Hypotension, hypoxia, and reduction of cardiac output may occur acutely, leading to impaired cerebral perfusion in the face of increased intracranial pressure or vasospasm. Neurogenic pulmonary edema, characterized by increased permeability of the pulmonary vasculature, may occur in isolation or in combination with neurogenic cardiac injury.

Fever

Fever, the most common medical complication of SAH, develops in 80% of patients at some time and may result from infection or "central" fever. Poor-grade patients with intraventricular blood often experience sustained fever that can lead to worsening of level of consciousness and exacerbation of ischemic injury caused by vasospasm. For these reasons, aggressive fever control in SAH patients with surface or intravascular cooling systems are recommended.

Anemia

SAH leads to a contraction of red blood cell mass. Combined with phlebotomy and volume resuscitation, all patients become progressively anemic during the first 10 days after SAH, and 20% to 40% require blood transfusions. Anemia has been linked to poor outcome after SAH, but it remains unclear if this is a cause or consequence of disease severity. With symptomatic vasospasm, even mild anemia (serum hemoglobin <10 mg/dL) can cause reduced oxygen delivery to ischemic brain tissue and should be avoided.

TREATMENT

The initial goal of treatment is to prevent rebleeding by excluding the aneurysmal sac from the intracranial circulation while preserving the parent artery and its branches. Once the aneurysm has been secured, the focus shifts toward monitoring and treating vasospasm and other secondary medical complications of SAH. This is best performed in an intensive care unit.

Emergency Management

The diagnosis of SAH is almost always made in the emergency department. Management at this juncture should focus on (1) minimizing ongoing brain injury in poor-grade patients with mental status changes and (2) reducing the risk of aneurysm rebleeding prior to an effective repair procedure. In Hunt-Hess grades IV and V patients, the immediate concern is ensuring adequate perfusion and oxygenation of the brain. Patients with impaired ability to protect the airway should be intubated, supplemental oxygen should be given as needed, and hypotension should be treated aggressively with fluids and vasopressors to maintain a mean arterial pressure of 90 mm Hg. Stuporous or comatose patients with extensive SAH or intraventricular blood on CT should be empirically treated for intracranial hypertension with 1.0 g/kg of 20% mannitol prior to placement of an external ventricular drain. Medical interventions that may reduce the risk of acute aneurysm rebleeding include control of arterial hypertension (systolic blood pressure <160 mm Hg), intravenous (IV) loading with an antifibrinolytic agent (epsilon aminocaproic acid 4 g followed by 1 g/h until 4 h prior to angiography, for a maximum of 72 h after SAH onset) LEVEL 1,[1] and administration of an anticonvulsant to minimize the risk of acute seizure activity (a loading dose of levetiracetam 2 g IV or phenytoin 20 mg/kg IV is most commonly used).

Surgical Management

In the 1980s, neurosurgeons began to abandon the traditional practice of delaying surgery until several weeks after aneurysmal rupture, in favor of early clipping within 48 to 72 hours. This change in practice became feasible with safer microsurgical techniques. Nonetheless, surgery still remains hazardous, with a 5% to 10% risk of major morbidity or mortality in most cases;

FIGURE 40.5 **A:** Cerebral angiogram demonstrates a left-pointing, 3-mm, midbasilar aneurysm *(arrow)* and vasospasm of both vertebral arteries *(arrowhead)*, the distal basilar artery, and the proximal right posterior cerebral artery. **B:** Significant increase in luminal diameter of the right vertebral artery after balloon angioplasty *(arrows)*. **C:** Microcatheter positioned at the neck of the midbasilar aneurysm. **D:** Midbasilar aneurysm *(arrow)* with no residual filling after packing with a single platinum detachable coil. (Courtesy of Dr. Huang Duong.)

smaller aneurysms have a lower risk of procedural complications than larger aneurysms. Besides preventing early rebleeding, early surgery also permits aggressive treatment of vasospasm with hypertensive hypervolemic therapy, which can be dangerous with an unprotected aneurysm. Although early surgery was at one time reserved for patients in good clinical condition (Hunt-Hess grades I to III), this approach has been extended to all but the most moribund patients. The advent of endovascular coil embolization has been a major advance because it is a treatment option for high-risk patients who are not good candidates for early surgery.

The management of asymptomatic unruptured aneurysms is controversial. Most neurosurgeons recommend surgery for aneurysms larger than 5 mm, as long as the hoped-for benefit of surgery (reduced lifetime risk of bleeding) outweighs the risks. In good hands, the risk of major morbidity or mortality from clipping of an unruptured aneurysm is 2% to 5%; the risk is highest for large aneurysms and for aneurysms of the basilar artery.

Endovascular Therapy

Endovascular coil embolization, introduced in the early 1990s, is a safe and effective alternative to surgical clipping for treating ruptured intracranial aneurysms. Endovascular packing of aneurysms (Fig. 40.5) with soft, thrombogenic detachable platinum coils leads to nearly complete obliteration of smaller aneurysms (<12 mm in diameter) in 80% to 90% of cases, with an acceptable complication rate of approximately 9% (see Chapter 25). The long-term risk of postprocedural rebleeding is minimal after successful clipping or coiling, and there is fairly compelling evidence that the less invasive coiling procedure is safer. In the International Subarachnoid Aneurysm Trial, 2,143, SAH patients with predominantly small (<10 mm) anterior circulation aneurysms were randomly assigned to clip or coil therapy. Those treated with coils were 23% less likely to be dead or disabled 1 year later (Fig. 40.6) LEVEL 1.[2] Reasons for the observed improvement in outcome with coils are unclear but may include lower risk of perioperative rebleeding, reduced physical manipulation of the brain, less delayed ischemia from vasospasm, or other unidentified factors.

Aneurysms with wide necks are less amenable to coil embolization because it is harder for the aneurysmal sac to contain the coil. With wide neck saccular aneurysms, it is sometimes necessary to place a stent in the parent vessel across the aneurysm neck and deploy coils through the stent (stent-assisted coiling). For shallow "blister" aneurysms, or very large aneurysms that involve a substantial portion of the circumference of the parent artery, a dense flow-diverting (Pipeline) stent can be placed across the diseased arterial segment, with excellent angiographic results. Data on the long-term efficacy of these advanced endovascular techniques are lacking.

The main disadvantage of endovascular treatment is the requirement for periodic reevaluation to ensure durable occlusion of the aneurysm. Approximately 5% of coiled patients develop recurrent dilations at the neck of the original aneurysm and that requires repeat coil embolization or delayed surgical clipping.

FIGURE 40.6 Distribution of modified Rankin Scale (mRS) outcome scores in the International Subarachnoid Aneurysm Treatment Trial, which compared surgical clipping to endovascular coiling as the primary treatment for subarachnoid hemorrhage due to ruptured intracranial aneurysm. The results showed that 190 of 801 (23.7%) patients allocated to coil treatment were dependent or dead at 1 year (mRS 3-6), compared with 243 of 793 (30.6%) allocated neurosurgical clipping ($P = .0019$).

TABLE 40.6 Critical Care Management Protocol for Acute Subarachnoid Hemorrhage (SAH)[a]

Blood pressure	• Control elevated blood pressure during the preoperative phase (systolic blood pressure <160 mm Hg) with IV labetalol, nicardipine, or clevidipine to prevent rebleeding.
Rebleeding prophylaxis	• Epsilon aminocaproic acid 4 g IV upon diagnosis followed by 1 g/h until aneurysm repair, for a maximum of up to 72 h after ictus
IV hydration	• Normal (0.9%) saline or a balanced isotonic solution (ie, Plasma-Lyte) at 1.0-1.5 mL/kg/h
Laboratory testing	• Periodically check complete blood count and electrolytes. • Obtain serial ECGs and check admission cardiac troponin I (cTI) to evaluate for cardiac injury; perform echocardiography in patients with abnormal ECG findings or cTI elevation.
Seizure prophylaxis	• Fosphenytoin (15-20 mg/kg) or levetiracetam 2 g IV; discontinue on postop day 1 unless patient has seized, is poor grade, or has focal cortical pathology or is otherwise unstable.
Vasospasm prophylaxis	• Nimodipine 60 mg orally every 4 h until day SAH 21 or discharge
Physiologic homeostasis	• Cooling blankets to maintain temperature ≤37.5°C • Insulin drip to maintain glucose 120-180 mg/dL • Transfuse to maintain hemoglobin >7.0 g/dL (in the absence or active cerebral or cardiac ischemia).
Ventricular drainage	• Emergent EVD placement in all stuporous/comatose patients (Hunt-Hess grade IV/V) as well as lethargic patients with hydrocephalus • Begin trials of clamping external ventricular drain and monitoring ICP on day 3 after placement. • Perform ventriculoperitoneal shunting during subacute phase of illness in patients with persistent cognitive dysfunction and ventriculomegaly.
Vasospasm diagnosis	• Transcranial Doppler sonography every 1-2 d until the 10th day after SAH • CT angiography on days 4-8 after SAH if high risk
Therapy for symptomatic vasospasm	• Place patient in Trendelenburg (head-down) position. • Infuse 500 mL 5% albumin or 1 L of 0.9% saline over 30 min. • If the deficit persists, raise the systolic BP with phenylephrine or norepinephrine until the deficit resolves (target 180-220 mm Hg). • If refractory, monitor cardiac output and add dobutamine or milrinone to maintain cardiac index ≥4.0 L/min/m^2. • Transfuse to maintain hemoglobin >10.0 g/dL. • Emergency angiogram for intra-arterial verapamil or cerebral angioplasty unless the patient responds well to the above measures

Abbreviations: CT, computed tomography; ECG, electrocardiogram; EVD, external ventricular drain; ICP, intracranial pressure; IV, intravenous.

Intensive Care Management

A suggested algorithm for the postoperative management of SAH is outlined in **Table 40.6**. All patients with SAH should be monitored in an intensive care unit, where neurologic examinations can be performed frequently. Blood pressure control can be liberalized once the aneurysm has been repaired and brain perfusion becomes the dominant consideration. Anticonvulsants are discontinued on the first postoperative day in good-grade patients who have not had a seizure; anticonvulsant prophylaxis is continued for approximately 1 week in poor-grade patients.

Most centers advocate the use of aggressive fluid resuscitation with isotonic crystalloid (with or without additional colloids) to prevent volume contraction, although this has not been proven to reduce the risk of symptomatic ischemia from vasospasm. Patients should receive isotonic fluid resuscitation (ie, 1 mL/kg/h of 0.9% saline) to maintain a euvolemic state guided by total fluid balance, central venous pressure, and other measures of volume status. The calcium channel blocker nimodipine reduced the frequency of delayed ischemic deterioration by about 30% in several clinical trials; this effect was attributed to reduction of calcium entry into ischemic neurons or by improvement in microcollateral flow because no effect on angiographic spasm was demonstrated LEVEL 1.[3]

Externalized ventricular drains are used to treat obstructive hydrocephalus in patients who are stuporous or comatose, but these devices carry a risk of infection (up to 10% overall) and therefore should be removed once intracranial pressure is stable during a 24-hour clamping trial.

Transcranial Doppler ultrasonography is widely used to diagnose vasospasm of the larger cerebral arteries after SAH. Accelerated blood flow velocities, which occur as flow is maintained through narrowed arteries, have a sensitivity and specificity of 90% for angiographic vasospasm of the proximal middle cerebral artery, but they are less sensitive for detecting spasm of the anterior cerebral or basilar arteries. Increased transcranial Doppler velocity does not imply increased likelihood of developing ischemia from vasospasm. For this reason, a CT perfusion scan is obtained between SAH days 4 and 8 to determine whether cerebral blood flow is regionally compromised.

Treatment of acute symptomatic vasospasm relies on increasing blood volume, blood pressure, and cardiac output in an attempt to improve cerebral blood flow through arteries that have lost the capacity to autoregulate. Hypertensive-hypervolemic-hemodilution ("triple-H therapy") of this type involves administration of isotonic crystalloid solutions to maintain central venous pressure greater than 10 mm Hg and pressors such as norepinephrine or phenylephrine to elevate systolic blood pressure to levels as high as 180 to 220 mm Hg. Hemoglobin levels of about 10 mg/dL are optimal for oxygen delivery, balancing the increase in cerebral blood flow that results from anemia and the increase in blood oxygen content that comes with higher

hemoglobin levels. In refractory poor-grade patients (Hunt-Hess grade IV and V), early goal-directed fluid therapy using transpulmonary thermodilution monitoring to maintain the cardiac index above 3 $L/min^1/m^2$ has been shown to reduce the risk of DCI and improve outcome compared to standard management LEVEL 2.[4] Hemodynamic augmentation results in clinical improvement in about 70% of patients. Rescue therapy with intra-arterial vasodilators (verapamil, nicardipine, or milrinone) or cerebral angioplasty can lead to dramatic improvement in patients with severe deficits that are refractory to hemodynamic augmentation (see **Fig. 40.4**).

Vasospasm can lead to clinically "silent" brain infarction in poor-grade patients who are stuporous or comatose and require sedation to assist in mechanical ventilation. To detect ischemia at its earliest stages, many centers rely on continuous electroencephalogaphic and invasive monitoring of brain tissue oxygen and cerebral blood flow to provide real-time information about the adequacy of cerebral perfusion and autoregulatory capacity (see also Chapter 34). Trends indicating a reduction in brain perfusion generally trigger a trial of induced hypertension or urgent referral for angiography.

OUTCOME

Approximately 20% of SAH patients treated at high-volume centers do not survive to discharge. In contrast to older patients indicating that delayed ischemia from vasospasm is the major cause of death and disability after SAH, most mortality today is related to the acute effects of hemorrhage in poor-grade patients (**Fig. 40.7**). Important risk factors for mortality or poor functional recovery after SAH include poor clinical grade, advanced age, large aneurysm size, aneurysm rebleeding, cerebral infarction from vasospasm, and global cerebral edema. Medical complications such as fever, hyperglycemia, and anemia have also been linked to poor outcome.

In contrast to the focal neurologic deficits that typically follow ischemic stroke, survivors of SAH are disabled primarily by cognitive impairment. Neuropsychological testing reveals long-term problems in memory, concentration, psychomotor speed, visuospatial skills, or executive function in 60% to 80% of SAH patients. Depression and anxiety are also common. These disturbances do not lead to the outward appearance of disability but can affect work, relationships, and quality of life; about 50% of SAH patients do not return to their previous level of employment. Cognitive and physical rehabilitation are essential for maximizing recovery in severely affected patients.

OTHER KINDS OF MACROSCOPIC ANEURYSMS

Fusiform or Dolichoectatic Aneurysms

These circumferential vessel dilations usually involve the carotid, basilar, or vertebral arteries. Atherosclerosis probably plays a role in their formation, but a developmental defect of the wall may be present in some. Fusiform aneurysms seldom become occluded with thrombus and rarely rupture. If bleeding occurs, treatment often requires proximal vessel occlusion.

Mycotic Aneurysm

Mycotic aneurysms are caused by septic emboli, which are most often formed by bacterial endocarditis (see Chapter 64). They are usually only a few millimeters in size and tend to occur on distal branches of pial vessels, especially those of the middle cerebral artery. Mycotic aneurysms have been reported in up to 10% of endocarditis patients, but arteriography is not routinely performed, and the incidence is probably underestimated. Pyogenic segmental arteritis from septic emboli in the

FIGURE 40.7 Mortality after subarachnoid hemorrhage (SAH) according to the primary cause of death or neurologic devastation leading to withdrawal of support. Data are from 3,521 patients enrolled in the Cooperative Aneurysm Study between 1980 and 1983 and 1,019 patients enrolled in the Columbia University Outcomes Project between 1996 and 2006. Numbers represent the percentage of all subarachnoid hemorrhage patients who died as a direct consequence of the listed variable. Abbreviations: ICP, intracranial pressure; OR, operating room. (From Komotar R, Schmidt JM, Starke RM, et al. Resuscitation and critical care of poor-grade subarachnoid hemorrhage. *Neurosurgery*. 2009;64[3]:397-410.)

absence of frank aneurysm formation can also lead to intracranial hemorrhage. Because rupture is fatal in 80% of patients with mycotic aneurysms, cerebral arteriography should be performed when endocarditis is accompanied by suspicious headaches, stiff neck, seizure, focal neurologic symptoms, or CSF pleocytosis. Although mycotic aneurysms occasionally disappear radiographically with antimicrobial therapy, the outcome cannot be predicted, and the aneurysm should be treated surgically as soon as possible.

Pseudoaneurysm

Dissection of an intracranial vessel, which usually results from trauma, can lead to extension of blood from the false lumen through the entire vessel wall. The extravasated blood is contained by either a thin layer of adventitia or the surrounding tissues and does not have a true aneurysmal wall; hence, the designation *pseudoaneurysm*. If a vessel traversing the subarachnoid space is affected, SAH can result. Treatment may require endovascular or surgical vessel occlusion or trapping, or angioplasty and stenting of the involved segment.

Vascular (Arteriovenous) Malformations

Vascular malformations account for less than 5% of all cases of SAH. Intracranial and spinal vascular malformations can be classified into five main types: (1) arteriovenous malformations (AVMs), which are high-flow and most often symptomatic; (2) dural arteriovenous fistulas (dAVF); (3) cavernous malformations; (4) capillary telangiectasias; and (5) venous malformations.

AVMs are a conglomerate of abnormal arteries and veins with intervening gliotic brain tissue; they resemble a "bag of worms." dAVFs are direct arterial to venous shunts that form in the walls of a dural sinus, that over time result in local venous hypertension and congestion.

SAH from brain vascular malformations is almost exclusively related to rupture of an AVM or dAVF. Many cases of SAH related to an AVM are caused by a feeding artery or intranidal saccular aneurysm, the former of which can be treated by clip or coil occlusion. SAH related to dAVF results from rupture of a vein in the subarachnoid space that has been subjected to arterialized flow. Dural and spinal cord AVMs and dAVFs should be kept in mind in patients with angiogram negative SAH. MRI of the head and neck can sometimes detect these malformations, especially if small or thrombosed. For more details on brain vascular malformations refer to Chapter 42.

41 Cerebral Venous and Sinus Thrombosis

Jennifer A. Frontera and Natalie Organek

KEY POINTS

1. Patients with cerebral venous thrombosis (CVT) can have a variety of clinical presentations including headache, focal neurologic deficits, seizure, abnormal mental status, and coma.
2. A CVT is a neurologic emergency with time-dependent treatments.
3. The diagnosis of CVT is confirmed radiographically. Computed tomography and magnetic resonance venograms are the most commonly used imaging tools.
4. The mainstay of CVT treatment is anticoagulation, even in the context of CVT-related intraparenchymal hemorrhage
5. Enoxaparin is likely a superior to unfractionated heparin for anticoagulation.
6. Patients who worsen despite adequate anticoagulation may be candidates for endovascular intervention including thrombectomy and intrasinus thrombolysis.

INTRODUCTION

Cerebral venous thrombosis (CVT) is thrombosis of the venous channels that drain blood from the brain (Fig. 41.1). The CVT includes both cerebral sinus thrombosis and cortical vein thrombosis. Often, it is associated with other conditions causing thrombi, but not infrequently, its cause remains unknown. The CVT commonly presents with isolated headache but also must be kept on the differential for causes of cerebral ischemia, hemorrhage, and even coma. The CVT image findings may be subtle but are important because overlooking them can have catastrophic consequences. Treatment recommendations for CVT had been controversial for many years, although anticoagulation remains the mainstay of treatment and endovascular therapies are becoming more common. Overall, the outcome for CVT is positive; if it is treated early, recurrence rates are low.

EPIDEMIOLOGY

The CVT is an uncommon disorder affecting a variable patient population. The CVT in adults is thought to affect about 5 to

FIGURE 41.1 Cerebral venous anatomy. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2014-2015. All Rights Reserved.)

15.7 people per 1 million every year. Most accounts estimate that CVT represents slightly less than 1% of all strokes. The International Study on Cerebral Vein and Dural Sinus Thrombosis (ISCVT), the largest multicenter collaboration of consecutively enrolled symptomatic CVT patients older than 15 years with imaging confirmation, collected data on 624 patients from 24 countries and 89 centers and found the following epidemiologic data for CVT: median age was 37 years (age range 16-86 y), and 74% of enrollees were female. These data are in keeping with the general belief that, although it can affect any age or sex, in the adult population, CVT is largely a disorder of young to middle-aged females. The preponderance of women affected may be related to hormonal risks associated with oral contraceptives, pregnancy, and puerperium.

The Canadian Pediatric Ischemic Stroke Registry (CPISR) is one of the largest pediatric CVT registries and involved 16 pediatric tertiary care centers in Canada collecting data on 160 consecutive cases of radiologically confirmed CVT in children 0 to 18 years old. These data demonstrated an incidence of pediatric CVT to be about 6.7 per 1 million people. Among the 160 children enrolled, 54% were younger than 1 year old (with 43% younger than 1 mo of age) and 54% were male. This follows the general understanding that the pediatric CVT population largely involves very young children, and the female preponderance seen in adult CVT is not present in pediatric CVT populations.

PATHOBIOLOGY

The CVT has been attributed to numerous causes, yet even after extensive workup, almost 30% of CVT diagnoses remain idiopathic. The ISCVT found that thrombophilia (34.1%) and oral contraception (54%, overall data corrected for females of childbearing age) accounted for a significant portion of the causes of CVT. Other important causes of CVT were puerperium (14%, overall data corrected for females of childbearing age) and pregnancy (6%, overall data corrected for females of childbearing age). Additionally, infection (especially of the ear, sinus, mouth, face, and neck) contributed to 12% of CVT cases in their data set, and malignancy (within and outside of the central nervous system, both solid tumor and hematologic) was found to have caused 7% of CVT in the ISCVT population. Regarding genetic causes, Marjot et al performed a meta-analysis of 26 studies. This included 1,183 CVT patients, explored six genes, and demonstrated a statistically significant association between CVT and two genes: factor V Leiden (odds ratio = 2.40; 95% confidence interval, 1.75-3.30; $P < .00001$) and prothrombin gene mutation (odds ratio = 5.48; 95% confidence interval, 3.88-7.74; $P < .00001$). Finally, more than 44% of subjects were found to have more than one cause of CVT, an important fact to remember when exploring causes of CVT in hopes of preventing reoccurrence. **Table 41.1** summarizes common causes of CVT.

In contrast to adult data, the most common cause of CVT in children is infection. In the CPISR data, acute infection was most commonly found in neonates (children younger than 1 mo; 84%). Perinatal complications (51%) and dehydration (30%) were also common causes of CVT in the neonatal population. In older children (older than 1 mo but younger than 18 y), chronic illness was the most common risk factor, especially connective tissue disorders (23%), hematologic disease (20%), and cancer (13%). Similar to the adult data, the CPISR data found prothrombotic states to be an important cause of CVT in neonates (20%) and children (54%).

TABLE 41.1 Common Causes of Cerebral Sinus Thrombosis

Drugs	Oral contraceptives (especially in combination with tobacco, obesity, and/or prothrombotic disease), hormone replacement therapy, fertility medications, asparaginase chemotherapy, tamoxifen, steroids, androgens
Hematologic diseases	Polycythemia, thrombocythemia, paroxysmal nocturnal hemoglobinuria
Hypercoagulable state	Protein C, S, or antithrombin III deficiency; factor V Leiden mutation; prothrombin gene mutation; antiphospholipid syndrome (lupus anticoagulant/anticardiolipin antibody); nephrotic syndrome; hyperhomocysteinemia
Infections	Encephalitis; cerebritis; meningitis; mastoiditis; otitis; sinusitis; infections of the mouth, face, and neck
Inflammatory diseases	Vasculitis, lupus, Wegener granulomatosis, polyarteritis nodosa, inflammatory bowel disease, Behçet disease, thromboangiitis obliterans, sarcoidosis
Malignancy	CNS tumors with invasion of the venous sinus, hematologic cancers, myeloproliferative syndromes, nasopharyngeal cancers, meningioma, head and neck tumors, hypercoagulable state due to malignancy
Obstetric	Pregnancy and puerperium
Trauma (including iatrogenic)	Head injury, lumbar puncture, neurosurgical procedures
Cerebrovascular abnormalities	Dural arteriovenous fistula

Abbreviation: CNS, central nervous system.

CLINICAL FEATURES

The variable clinical presentation is one of the challenges of CVT. The two main mechanisms by which CVT causes symptoms are (1) obstruction of venous drainage leading to increased venous pressure, disruption of the blood brain barrier, vasogenic edema, and ischemic or hemorrhagic stroke; and (2) elevated venous pressure resulting in reduced resorption of cerebral spinal fluid by arachnoid granulations with consequent hydrocephalus and/or elevated intracranial pressure (ICP). Increased cerebral blood volume due to reduced venous drainage will also contribute to elevated ICP.

Diffuse progressive headache over hours to days is the most common presentation in patients with CVT, although thunderclap and migrainous-type headache have also been described. Importantly, isolated headache without other neurologic findings or signs of elevated ICP occurred in 25% of confirmed CVT in the ISCVT cohort. It is important to consider that persistent headache following lumbar puncture could be CVT because, rarely, spinal fluid drainage can precipitate CVT.

When CVT does cause an increase in ICP, patients commonly present with the following neurologic signs: papilledema, diplopia (most commonly due to sixth nerve palsy), headache which worsens with recumbency, nausea/vomiting, and encephalopathy. Because symptoms of idiopathic intracranial hypertension

often mimic those of CVT, it is critical to evaluate for CVT when idiopathic intracranial hypertension is suspected.

In addition to signs of increased ICP, focal neurologic deficits following cerebral ischemia or hemorrhage are also important clinical presentations in patients with CVT. Indeed, 30% to 40% of CVT patients present with intracerebral hemorrhage. The actual signs of the focal brain injury are attributed to the site of venous ischemia and are therefore variable but include focal weakness, sensory changes, visual field deficits, and aphasias. Further confounding this picture in CVT, the superior sagittal sinus, the most commonly involved cerebral venous structure in CVT, drains both cerebral hemispheres and therefore when thrombosed can cause bilateral deficits complicating neurologic localization. A small yet clinically important subset of CVT patients are those with deep CVT. A CVT affecting the basal ganglia or thalamus is commonly bilateral and can lead to venous ischemia or hemorrhages. A CVT affecting the deep parts of the brain tends to be more severe and quickly results in profound deficits including altered mental status and coma.

Seizures may also occur in the context of CVT. In ISCVT, seizures occurred in 39% of patients. In children, seizures have been reported in 44% of CVT patients.

The cavernous sinuses are a unique set of cerebral sinuses. They are deep bilateral structures at the base of the cerebrum that house the internal carotid artery, ophthalmic vein, branches of the sphenoid, and superficial middle cerebral veins as well as cranial nerves III, IV, V1, V2, and VI. Venous thromboses affecting the cavernous sinuses are associated with palsies affecting these cranial nerves leading to diplopia and ophthalmoparesis as well as pain, ptosis, chemosis, and proptosis. Increased intraocular pressure due to poor venous drainage can lead to papilledema and loss of visual acuity. Fever, periorbial edema, and sensory loss in cranial nerves V1 and V2 distributions may occur. Most cavernous sinus thromboses are related to infection, typically due to *Staphylococcus aureus*, although *Streptococcus pneumoniae*, gram-negative rods, anaerobes, and occasionally fungal infections may be culprits. Venous drainage from the facial veins and pterygoid plexus via the superior and inferior ophthalmic veins provide a route for the spread of facial infections to the cavernous sinus, which is highly trabeculated and can act as a repository for bacteria. Sphenoid and ethmoid sinus infections can also lead to septic thrombosis of the cavernous sinus. Otitis media, dental, and mastoid infections can rarely be associated with cavernous vein thrombosis. Noninfectious causes of cavernous sinus thrombosis include Tolosa-Hunt syndrome (granulomatous inflammation of the cavernous sinus and superior orbital vein), Cogan syndrome (polyarteritis nodosa with CVT), trauma, meningioma, and nasopharyngeal tumor. Spread of symptoms to the contralateral eye via the intracavernous sinuses may occur within 24 to 48 hours of the initial presentation and is pathognomonic for cavernous sinus thrombosis.

Septic lateral sinus thrombosis can occur in the context of mastoiditis and typically involves the sigmoid sinus with extension to the transverse sinus and jugular vein. Secondary hydrocephalus can occur if the dominant transverse sinus is involved because the final common pathway of cerebral spinal fluid resorption from the arachnoid granulations is through the sagittal sinus, sigmoid sinus, and jugular vein. Fluent aphasia may be a presenting feature of left-sided (or dominant) lateral sinus thrombosis. Multiple cranial neuropathies and/or pulsatile tinnitus can be presenting features of lateral sinus and/or jugular vein thrombosis. Gradenigo syndrome is a triad of otitis media, sixth nerve palsy, and temporal/retroorbital pain and is highly suggestive of lateral sinus thrombosis. The most common organisms involved in lateral sinus thrombosis are *Proteus* species, *S aureus*, *Escherichia coli*, *Pseudomonas*, and anaerobic species.

TABLE 41.2 Common Cerebral Venous Thrombosis Syndromes

CVT Location	Symptoms
Superior sagittal sinus	Large vein, symptoms depend on location affected Motor deficits (can be bilateral due to central location) Psychiatric symptoms (when affecting the frontal lobes) Seizures due to cortical location
Transverse sinus	Aphasias when they affect areas of speech
Cerebral cortical vein	Deficit varies depending on location of CVT. Seizures due to cortical location
Deep venous system	Change in mental status Coma Bilateral deficits due to central location
Cavernous sinus	Palsies affecting cranial nerves III, IV, V1, V2, or VI Orbital pain, chemosis, proptosis, papilledema, decreased visual acuity

Abbreviation: CVT, cerebral venous thrombosis.
Adapted from Frontera J, ed. *Decision Making in Neurocritical Care*. New York, NY: Thieme; 2009.

Table 41.2 summarizes common syndromes associated with CVT.

Clinical presentation for CVT in children is similar to adults except in neonates where seizure is more common. In the CPISR database, 71% of neonates (children younger than 1 mo old) with CVT had seizure attributed to CVT, in contrast to only 48% of nonneonate CPISR children and 44% of CVT patients older than 15 years.

DIAGNOSIS

The CVT is a pathology known for its infrequent as well as variable clinical presentation both of which can complicate diagnosis. Delays in diagnosis of CVT are not uncommon; therefore, a high level of suspicion must be maintained in the proper clinical context. Diagnosing CVT begins with a thorough patient history and physical examination. Elements discovered in these investigations help to determine the necessary laboratory and radiologic evaluation.

The key to diagnosis in CVT is direct imaging of the cerebral venous system. Both computed tomography venography (CTV) and magnetic resonance venography (MRV) have been studied in CVT; they have been found to be equivalent imaging techniques in CVT. Figure 41.2A demonstrates CVT in the torcula on T2 magnetic resonance imaging (MRI) and in the left transverse sinus on MRV (Fig. 41.2B, *white arrows*). Figure 41.3 shows an MRV with a complete filling defect of the superior sagittal sinus from the origin to the torcula. Drawbacks associated with CTV include radiation exposure, contrast allergy, and limited use in renal failure. The MRV is limited in patients with pacemakers and requires significant time that is typically unavailable in urgent neurologic evaluations. Distinguishing thrombosis

FIGURE 41.2 Axial T2 magnetic resonance imaging **(A)** and coronal magnetic resonance venography **(B)** demonstrating a thrombus at the torcula (*white arrow* in **A**) and at the transverse sinus (*white arrow* in **B**).

from venous hypoplasia (particularly of the transverse sinus) or venous arachnoid granulations can complicate interpretation of MRV and CTV imaging. Parenchymal MRI sequences can be useful in making this distinction (**Table 41.3**) and is particularly useful for diagnosing cavernous sinus thrombosis.

FIGURE 41.3 Sagittal time of flight magnetic resonance venography demonstrating complete filling defect of the superior sagittal sinus from the origin to the torcula in a woman with a history of fertility injections, oral contraceptive use, tobacco use, and leiomyoma. There is also a filling defect in the midtransverse sinus *(white arrow)*. Note the prominent cortical venous drainage that has developed to compensate *(small black arrows)*.

Conventional digital subtraction angiography was the gold standard for the diagnosis of CVT for many years, although, for the most part, it is currently reserved for inconclusive CTV or MRV imaging or when endovascular intervention is required. In patients with persistent symptoms or those with previously diagnosed CVT and a change in symptoms, repeat imaging should be considered to evaluate for new CVT as well as propagation of known thrombus. Digital subtraction angiography may be particularly useful for suspected cortical vein thrombosis, where MRV and CTV resolution is limited. **Figure 41.4A** shows a digital subtraction angiogram with partial superior sagittal sinus thrombosis and proliferation of cortical venous drainage as well as prominent deep venous drainage. A follow-up MRV 1 month after endovascular treatment shows a patent superior sagittal sinus (**Fig. 41.4B**).

In 2011, the American Heart Association (AHA) and the American Stroke Association (ASA) created the statement for health care professional on the diagnosis and management of CVT LEVEL 1,[1] which reviewed, among other topics, invasive and noninvasive CVT diagnostic imaging modalities. In the AHA/ASA review, noncontrast CT of the brain was the most common imaging modality for patients with new neurologic symptoms.

TABLE 41.3 Using Magnetic Resonance Imaging to Age Cerebral Blood

Phase	Time	T1	T2	Hemoglobin
Acute	1-3 d	Isodense	Dark	Deoxyhemoglobin
Early subacute	3-7 d	Bright	Dark	Methemoglobin
Late subacute	7-14 d	Bright	Bright	Methemoglobin
Chronic	>14 d	Dark	Dark	Hemosiderin

Adapted from Frontera J, ed. *Decision Making in Neurocritical Care.* New York, NY: Thieme; 2009.

FIGURE 41.4 Sagittal digital subtraction angiography **(A)** and magnetic resonance venography **(B)** in a patient with partial sagittal sinus thrombosis (*thick white arrow*, **A**). Note the compensatory hypertrophied and corkscrew cortical venous drainage (*thin white arrow*, **A**) and prominent deep venous drainage (internal cerebral vein, *thick black arrow* in **A**; vein of Galen, *thin black arrow* in **A**; and straight sinus, *thick gray arrow* in **A**). One month following endovascular thrombectomy and intrasinus tPA infusion, the magnetic resonance venography **(B)** demonstrates a patent superior sagittal sinus. The internal cerebral vein (*thick black arrow* in **B**), vein of Galen (*thin white arrow* in **B**), and straight sinus (*thick white arrow* in **B**) are still easily visualized. Abbreviation: tPA, recombinant tissue plasminogen activator.

Noncontrast head CT is often unremarkable but may demonstrate subtle signs suggestive of the CVT, namely, hyperdensities in the cerebral veins. This finding is present in only about one-third of patients. The most well-known noncontrast head CT finding in CVT is the dense triangle found in the posterior sagittal sinus called the *filled delta sign*. There is often a delay in visualization of this sign for days, but once present, it typically persists for weeks, which make it likely to be most helpful with late presentation of CVT. The noncontrast head CT in Figure 41.5 demonstrates a hyperdense clot in the left transverse sinus (*white arrow*). More often, noncontrast head CT demonstrates nonspecific indirect signs of CVT including CT hypodensities and a decrease in ventricular size both associated with parenchymal edema. Nonenhanced head CT is also helpful in demonstrating cerebral venous infarctions or intracerebral hemorrhage, which characteristically are in vascular distributions inconsistent with more common arterial disease. Perhaps most importantly, noncontrast CT is helpful in ruling out other causes for the clinical presentation. In CVT, contrast-enhanced CT may demonstrate the "empty delta sign" wherein the thrombus creates a filling defect in the cerebral venous system and, therefore, becomes "empty." The overall accuracy of head CT and CTV in combination is 90% to 100%. Finally, as with most cerebrovascular disease, MRI of the brain can be helpful in demonstrating earlier signs of venous infarct associated with CVT.

A CVT laboratory workup is focused on determining the cause and should include basic labs as well as an evaluation for hypercoagulability. Anticoagulation can affect the outcome of the hypercoagulable labs, and therefore, these should be examined prior to initiating anticoagulation treatment for CVT. Table 41.4 lists laboratory workup for CVT.

FIGURE 41.5 Noncontrast head computed tomography demonstrates a left transverse sinus thrombosis *(white arrow)*.

TABLE 41.4 Laboratory Workup for Cerebral Venous Thrombosis (CVT)

Basic labs	CBC, chemistry, liver function testing, antinuclear antibody, D-dimer (elevated levels support the diagnosis, but normal levels do not exclude CVT)
Hypercoagulable workup (test prior to starting anticoagulation)	PT/INR, aPTT, homocysteine, methylmalonic acid, MTHFR gene mutation, factor V Leiden mutation, prothrombin gene mutation, antiphospholipid and anticardiolipin antibodies, lupus anticoagulant, protein C and S levels and activity, antithrombin III levels, factor VIII level, fibrinogen, B2 glycoprotein
Specific testing (patient specific)	Urine protein (if nephrotic syndrome is suspected)

Abbreviations: aPTT, activated partial thromboplastin time; CBC, complete blood count; INR, international normalized ratio; PT, prothrombin time.

D-dimer has been explored as a possible diagnostic marker for CVT, but high pretest probability remains paramount. Meng et al performed a prospective study of confirmed CVT in 94.1% of patients who had elevated D-dimer and during the acute phase, the sensitivity and specificity of predicting CVT with D-dimer were 94.1% and 97.5%. Similarly, in a meta-analysis of 1,134 CVT cases by Dentali et al, D-dimer was found to have a mean sensitivity of 93.9% and mean specificity of 89.7%. The AHA/ASA CVT statement LEVEL 2[1] reviewed sensitivity and specificity of a number of studies exploring D-dimer and CVT and suggests D-dimer may be helpful in those with very low suspicion of CVT but cannot be used to preclude further evaluation in patients in whom there is a strong clinical suspicion.

Diagnosis of CVT in children is similar to adults in that, most importantly, although CVT is rare and has a nonspecific presentation, it must not be left off a comprehensive differential in children with appropriate neurologic symptoms. As described earlier, this may be especially challenging in neonates who more commonly present with seizure but have otherwise nonspecific presentation. In general, CVT imaging is very similar in children and adults, but neonatal physiologic differences must be considered. The hypointensity of the immature unmyelinated brain as well as the hyperintensity of physiologic polycythemia associated with neonates can mimic the "delta sign" and is therefore known as the *pseudodelta sign*. This CVT mimic in neonates is easily clarified with administration of contrast material. Additionally, in neonates, transfontanellar ultrasound has been explored for CVT diagnosis but was generally found unreliable especially in nonocclusive thrombus and therefore has limited use in neonatal CVT without confirmation with other imaging modalities.

MANAGEMENT

The CVT treatment is typically trimodal: The mainstay of treatment is (1) anticoagulation, (2) treatment of the underlying etiology when appropriate (ie, antimicrobial for cases involving infection), and (3) symptomatic treatment (headache management, addressing increased ICP). In patients who present with seizure, antiepileptic drugs (AEDs) are indicated. Endovascular therapies should be considered in patients who fail anticoagulation or have extensive symptomatic CVT.

Anticoagulation Therapy

Anticoagulation is essential for preventing CVT propagation and to prevent systemic thrombosis in those with underlying hypercoagulable states. Einhäupl et al studied 20 patients with CVT (confirmed on imaging) who were randomized to intravenous unfractionated heparin (UFH) versus placebo. The study was stopped prematurely due to the obvious benefit of treatment with anticoagulation. Additionally, this group documented two intracerebral hemorrhages, both in the placebo group (none among the anticoagulation treatment group). Subsequently, in a study by de Bruijn et al LEVEL 2,[2] 59 patients with CVT were randomized to low molecular weight heparin (LMWH) versus placebo. The placebo group was more likely to have a poor outcome compared with the treatment group, and no intracerebral hemorrhages occurred in either group. The 2011 AHA/ASA guidelines for CVT recommend initial anticoagulation with UFH or weight-based LMWH in full doses followed by vitamin K antagonists regardless of the presence of intracerebral hemorrhage LEVEL 1.[1] In 2012, the American College of Chest Physicians formally recommended initial treatment for CVT with either dose-adjusted heparin or LMWH followed by oral anticoagulation for 3 to 6 months for most patients and lifelong anticoagulation for CVT patients with permanent risk factors for recurrent events LEVEL 1.[3] Similarly, the 2014 AHA/ASA guidelines for prevention of stroke LEVEL 1[4] and the 2017 European Stroke Organization guidelines both recommend acute anticoagulation regardless of the presence of intracerebral hemorrhage. The 2017 European Stroke Organization guidelines recommend using LMWH over UFH LEVEL 1.[5] It is important to note that anticoagulation *should be administered for CVT even in the context of intracranial hemorrhage*.

An LMWH may be preferred over UFH in patients who do not require urgent surgical intervention. The ISCVT investigators compared the outcomes of CVT patients treated with UFH and LMWH and found a better efficacy and safety for LMWH. Additionally, a randomized controlled trial of 66 CVT patients also explored treatment with UFH and LMWH and found LMWH to have a significantly lower mortality in CVT compared to UFH LEVEL 1.[6] Finally, women of childbearing age with CVT present a unique challenge. In women with a history of CVT, oral contraceptives should generally be avoided, and in pregnant women with a history of CVT, prophylaxis with LMWH during future pregnancies and in the postpartum period may be reasonable LEVEL 1.[7] Anticoagulation is generally continued for 3 to 6 months in provoked CVT and 6 to 12 months in unprovoked CVT using warfarin but may be continued longer in patients with long-term risk factors including thrombophilia. There is little data regarding the use of direct oral anticoagulants for long-term anticoagulation in CVT, although off-label use has been increasing.

Endovascular Therapy

The data for endovascular invasive therapy, including direct endovascular thrombolysis and thrombectomy, to this point has not proven to provide greater benefit than anticoagulation alone. The thrombolysis or anticoagulation for cerebral venous thrombosis (TO-ACT) LEVEL 1[8] randomized controlled trial of anticoagulation versus endovascular intervention in high-risk CVT patients was stopped early for futility. However, in patients with CVT who clinically deteriorate while on anticoagulation and in those who have an absolute contraindication to anticoagulation (such as hemodynamically significant hemorrhage or allergy to

FIGURE 41.6 **A:** Sagittal digital subtraction angiography demonstrates complete occlusion of the superior sagittal sinus from the origin to the torcula. Note clots present in the transverse and straight sinuses (*black arrows* in **A**). **B:** An overlay of normal arterial angiography *(white)* and the venous drainage pattern with diffuse cerebral venous thrombosis in the same patient. **C:** Improved venous flow following endovascular thrombectomy with recanalization of the superior sagittal sinus and torcula (*large white arrow* in **C**). There is improved flow in the straight sinus (*small white arrow* in **C**); however, some irregularity remains at the transverse-sigmoid sinus junction (*small black arrow* in **C**).

anticoagulation agents), endovascular intervention may be considered. Options for endovascular treatment include local infusion of recombinant tissue plasminogen activator as well as mechanical thrombolysis using balloons and rheolytic catheters. A systematic review of 42 studies with 185 patients reported a good outcome in 84% of CVT patients who underwent a variety of endovascular therapies including balloon angioplasty, clot retrieval, and thrombolysis with a 95% recanalization rate. However, worsened intracerebral hemorrhage occurred in 10% and mortality rates were 12%. Figure 41.6 shows the digital subtraction angiogram of a patient with extensive superior sagittal sinus thrombosis from the origin to the torcula. The patient remained symptomatic despite anticoagulation and underwent endovascular thrombectomy with recanalization of the superior sagittal sinus and torcula (panel C). In light of the recent advances in endovascular therapy, open surgical treatment for CVT is limited mostly to those patients with large cerebral venous infarcts who develop clinical and radiologic signs of herniation and may benefit from decompressive hemicraniectomy or minimally invasive clot removal.

Treatment of Comorbid Conditions

In patients with symptomatic intracranial hypertension, efforts to lower ICP should be considered. Elevation of the head of the bed with the head midline to promote venous drainage, osmotic therapy, and management of hypermetabolic states (shivering, fever, seizure, agitation) should be considered as part of routine intracranial hypertension management.

In patients with seizure related to CVT, AEDs should be administered LEVEL 7[1]; however, prophylactic AED use is not advised. The optimum duration of treatment with AEDs in CVT patients with seizure remains unknown.

In cases of septic thrombosis (eg, septic cavernous sinus thrombosis), antibiotics are a mainstay of treatment. Typical treatment regimens should cover *S aureus* and include vancomycin, ceftriaxone, or cefepime (if *Pseudomonas* is suspected). Anaerobic coverage for dental or sinus infections should include metronidazole. There is no evidence supporting the use of glucocorticoids for septic cerebral sinus thrombosis.

Treatment of Cerebral Venous Thrombosis in Children

There is a dearth of data regarding treatment of CVT in children; treatment guidelines are largely extrapolated from adult data. The AHA/ASA LEVEL 7[1] current recommendations for treating CVT in children older than 1 month of age align with adult recommendations for treatment with anticoagulation even in the context of intracerebral hemorrhage. Treatment recommendations for children younger than 1 month of age remain controversial and variable. Neonates should be treated with anticoagulation for 6 weeks to 3 months with close imaging follow-up to assess for recanalization with low threshold for stopping anticoagulation at 6 weeks if the venous system recanalizes LEVEL 7.[1] The AED recommendations in children (and neonates) are similar to that of adults.

OUTCOME

Overall, the outcome for most patients with CVT is positive, but there remains an important minority in whom the disease causes significant morbidity and mortality. According to ISCVT data, about 87% of CVT patients had complete recovery, but about 8% had significant morbidity with an additional mortality rate of about 5%. Similarly, Borhani Haghighi et al investigated a national cohort of almost 3,500 CVT patients had a mortality rate of 4.39%. Certain characteristics have been found to be associated with poor outcome in CVT including male gender, age older than 37 years, those with significant neurologic deficit and coma, as well as those who develop seizure. In the acute phase of CVT, brain herniation attributed to CVT remains the most common cause of death; in the late stages, mortality associated with

CVT is mostly related to the underlying cause of the thrombosis. Rates of CVT recurrence range from 2% to 4%. Recanalization rates in patients treated with anticoagulation are as high as 85% based on a meta-analysis of retrospective studies.

In childhood, CVT coma has been shown to predict mortality, but overall, few studies have followed children for more than 2 years after CVT. In the CPISR data (with only over 2 y of follow-up), approximately 75% of neonates and approximately 50% of nonneonates were neurologically normal.

Vascular Malformations 42

Fawaz Al-Mufti and Stephan A. Mayer

KEY POINTS

1. Arteriovenous malformations (AVMs) are congenital high-flow arteriovenous shunts, which can rupture.
2. Because bleeding often originates from the venous side, AVM hemorrhages are typically less severe than hypertensive intracerebral hemorrhage.
3. The most important risk factors for AVM hemorrhage are a previous bleeding event, small size, deep location, a single draining vein, and the presence of a feeding artery aneurysm.
4. Treatment of AVMs can be accomplished with surgical excision, arterial embolization, focused radiosurgery, or a combination of these modalities.
5. Dural arteriovenous fistulas are usually acquired lesions in which meningeal arteries connect directly to veins on the wall of a dural venous sinus.
6. Caverous malformations are small (<1 cm) low flow vascular anomalies. They are characterized by "target" lesions on MRI and are not visualized by angiography.

INTRODUCTION

This chapter deals with a heterogeneous group of central nervous system vascular lesions, including true vascular malformations such as arteriovenous malformations (AVMs) and cavernous malformations, acquired arteriovenous fistulas, vascular neoplasms, and other rare vascular disorders.

ARTERIOVENOUS VASCULAR MALFORMATIONS

AVMs are the most common of these rare disorders. They are thought to be congenital, arising in the prenatal period, but do not present clinically until middle life. Although many remain static anomalies, others enlarge in size and proliferate in vascular complexity, driven by incompletely understood pathophysiologic forces.

Epidemiology

AVMs are rare, occurring with a prevalence of 18 per 100,000, and a new AVM is discovered in approximately 1.5 per 100,000 individuals per year. Every year, about 1 out of every 100 people with an AVM will experience a hemorrhage. AVM symptoms tend to occur early in life; two-thirds of AVMs become symptomatic before age 40 years. Among pregnant women with an AVM, the annual bleeding risk is increased from 1.3% to 5.7%.

Pathobiology

Most AVMs are thought to be sporadic congenital developmental vascular lesions arising in the prenatal period. Well-documented reports of de novo brain AVM formation indicate that in some cases, AVMs can form later in life. A few are caused by brain contusions, which enlarge from normal tiny arteriovenous shunts. In genetic studies, specific polymorphisms of the NOTCH4 gene, which controls the normal development of vessels and proper arteriovenous specification, have been linked to AVM formation and rupture. Abnormalities of vascular endothelial growth factor and transforming growth factor (TGF)-β are also implicated in the creation of AVMs.

Whether congenital or acquired, AVMs are anatomically limited to the brain, spinal cord, or dura. Those embedded in the brain are most common, and 90% of these are supratentorial. The angioarchitecture of brain AVMs involves direct arterial to venous connections without an intervening capillary network. This vascular tangle, also referred to as the *vascular nidus*, resides within gliotic brain and is comprised of irregularly sized thin walled vascular channels lacking the expected media of arteries. The location and size of AVMs varies widely. Some are limited to the surface of a cerebral hemisphere, are fed by a single small artery and drain into a single small vein. At the opposite extreme, others form a huge wedge from the brain surface through the white matter to the ventricular wall (schizencephalic AVM); some are so large they can occupy a large portion of one hemisphere. A few lie in the subcortical white matter, whereas others are others located within the deep structures (eg, basal ganglia or thalamus), brainstem, or spinal cord. Those on the brain surface lying in the border zone between the major cerebral arteries typically have a higher incidence of seizures but a lower hemorrhage rate than those deeper in the brain. Collateral flow from the adjacent dura may occur. Rarely, feeding arteries can stenose or occlude over time; for them moyamoya type changes can appear with collateral small vessel recruitment due to proximal feeding artery stenosis or occlusion. Those that penetrate to the ventricular wall often draw blood supply from the deep vasculature that normally supplies the basal ganglia. Venous drainage may be into superficial or the deep venous systems, and draining veins may be slightly or enormously distended due to high pressure and flow. AVMs are typically solitary; multiple AVMs occur in approximately 5% of cases.

Clinical Features

AVMs present most often with bleeding, less often with headaches or seizures, and occasionally with progressive gait disturbance, focal neurologic deficit, or cognitive decline. Abnormal flow dynamics leading to edema and gliosis and "steal" phenomena, resulting in ischemia of surrounding tissues, have been postulated to cause nonhemorrhagic clinical features. Although the notion "steal" of blood flow was easily inferred by the disproportionate

flood of contrast into large AVMs on angiography, more recent studies of regional cerebral blood flow have found no evidence of ischemia in tissues adjacent to AVMs, prompting a challenge to the notion of cerebral steal as a cause of focal symptoms.

The most feared complication of AVMs by far is hemorrhage. Approximately 50% of AVMs present with hemorrhage, and AVMs are the most common cause of spontaneous cerebral hemorrhage in children. When hemorrhage occurs, it affects the following regions: intracerebral (30%), intraventricular (30%), subarachnoid (15%), and various combinations (25%). Although it might be assumed that physical exertion can trigger a hemorrhage, no such correlation has been found. The hemorrhage usually arises within the nidus and, when limited in volume, displaces adjacent healthy brain with varying degrees of symptoms and signs. Compared with hypertensive intracerebral hemorrhage, the morbidity of AVM hemorrhage is much less devastating, which may be due to the fact that may AVM hemorrhages originate from rupture of venous draining vessels. For AVMs that drain to the ventricular wall, bleeding may originate from the venous aspect of the malformation and extend mainly into the ventricle, which presents as intraventricular hemorrhage with hydrocephalus and only minor injury to adjacent brain structures. Larger hemorrhages escape the nidus and dissect into healthy brain tissue like any primary brain hematoma.

Arteries feeding the AVM nidus may develop flow-related aneurysms, which may bleed separately, typically causing subarachnoid hemorrhage (SAH) syndromes. AVMs with a high-flow arteriovenous communication are frequently associated with venous varices and inflow or outflow aneurysms, which are found in 20% to 25% of cases. Feeding artery aneurysms can be a source of bleeding in patients with brain AVMs and are thought to worsen their prognosis. AVMs are the second most identifiable cause of SAH after brain aneurysms, accounting for 5% of all cases of SAH.

The annual hemorrhage risk of an unruptured AVM ranges from 1% to 2%. Death from the first hemorrhage ranges between 5% and 20%, depending primarily on the size of the hemorrhage and the presence of ventricular extension. When hemorrhage occurs, some destabilization of the fistula occurs, and it can set the stage for recurrent hemorrhage. Once a bleeding event has occurred, an AVM is more than 5 times more likely to bleed again during the first year, with an annual risk of hemorrhage ranging from 4% to 5%. Besides prior hemorrhage, important risk factors for bleeding from an AVM include deep location, small size, a single draining vein, an associated feeding artery aneurysm, and pregnancy.

Unruptured AVMs are associated with seizures in 8% of cases, and this risk increases to 20% following a hemorrhage. Seizures are primarily seen when the AVM is cortically located, large, with superficial venous drainage. Overall, approximately 25% of AVMs present with seizures as the initial symptom.

AVMs are sometimes associated with headaches. No distinctive features separate either the seizures or the types of headache (including migraine) from non-AVM causes. Although an attractive clinical maxim, recurrent headaches of the same side have not proved predictive of an AVM. The diagnostic yield of detecting an AVM in patients presenting with headache alone is extremely low (0.2%).

Diagnosis

The diagnosis of AVM can be made by magnetic resonance imaging (MRI) with high reliability, which characteristically demonstrates "flow voids" (Fig. 42.1). MRI also demonstrates the

FIGURE 42.1 T2-weighted magnetic resonance images of a 36-year-old patient with a large deeply situated right parietooccipital arteriovenous malformation manifesting as a large cluster of dark serpiginous flow voids. The patient had a history of two prior hemorrhage events and had been symptomatic with left hemiparesis and dysarthria at the time of the magnetic resonance imaging.

FIGURE 42.2 Anteroposterior view from arterial **(left)** and venous **(right)** phase of right internal carotid arteriogram of the same patient in **Figure 42.1** shows arterial supply from right middle cerebral artery including ascending lenticulostriate, the anterior cerebral artery, and the posterior cerebral artery. Venous drainage is both superficial and deep, with the deep drainage converging on a large complex of veins draining into the posterior superior sagittal sinus.

feeding and draining vessels, the nidus, and its relationship to surrounding tissue. A computed tomography (CT) scan is considered less helpful unless the AVM is calcified. The gold standard diagnostic test is a cerebral angiogram (Fig. 42.2; see also Chapter 25), which most accurately delineates the vascular supply and venous drainage pattern, and can identify high-risk features. A cerebral angiogram should be performed in patients who have clinical symptoms, a history of hemorrhage, or when surgery is being contemplated. In the case of conservatively managed AVMs, surveillance MRI can help analyze changes in the size of the AVM, and identify hemosiderin staining consistent with recent bleeding. Dural and cervical spinal cord AVM should be kept in mind in patients with radiographically unexplained SAH, requiring examination of the external carotid arterial supply and cervical vertebral arteries.

Treatment

Treatment depends on the location of the AVM and the age and condition of the patient. Direct microsurgical resection, endovascular glue embolization, and directed-beam radiation therapy with a linear accelerator or Gamma Knife are the main treatment modalities.

Unruptured Arteriovenous Malformations

With the advent of MRI, asymptomatic AVMs or those presenting only with headaches or seizures have become increasingly prevalent. The increasing discovery of these conditions before bleeding occurs long posed a management dilemma—whether to take the risk of eradicating the lesion, embedded as it is in brain, or await the natural history of hemorrhage, hoping that if it occurs, it will not much damage the adjacent tissues. The A Randomized trial of Unruptured Brain AVMs (ARUBA) indicates that unless hemorrhage occurs, delaying definitive therapy may be safer than proceeding with attempts to remove or eradicate an unruptured AVM. The trial randomized 226 patients with an unruptured AVM to medical management alone or to interventional therapy (any combination of surgery, embolization, or radiosurgery). After 5 years of follow-up, the rate of symptomatic stroke or death was 3.4 per 100 patient years (15 of 110 patients) with conservative management compared to 12.3 per 100 patient years (41 of 116) with invasive management (hazard ratio, 0.31; 95% confidence interval, 0.17-0.56) LEVEL 1.[1,2] Most of the excess morbidity in the interventional arm resulted from procedural complications.

The real-world applicability of lessons learned from the ARUBA has been challenged. Criticism of the trial has focused on the heterogeneity of the patient population, lack of standardization of the treatment arm, and a higher than expected complication rate with treatment. Available evidence indicates unruptured brain AVM intervention rates have not changed in the United States since the publication of ARUBA in 2013.

Vein of Galen malformations are a special AVM associated with the deep venous system, often with marked aneurysmal dilatation of the vein of Galen region. The arterial supply may be complex and difficult to occlude by intravascular or surgical techniques. Most present in neonates or young children. Arteriovenous shunting leads to cardiac failure and compression of the midbrain, which causes hydrocephalus. The currently accepted treatment of these lesions is embolization, occasionally followed by surgery.

Ruptured Arteriovenous Malformations

The Spetzler-Martin grading scale is used to stratify the risk of death or major complications from surgery (Table 42.1). Individualized decision making for intervention is complex and relies on clinical expertise, the specifics of the anatomy of the AVM, and the wishes of the patient. Surgery remains the most effective means of eradicating AVMs. For larger or more complex lesions, adjunct intravascular occlusive therapy using liquid embolics such as n-butyl cyanoacrylate can obliterate some AVM feeders, shrinking the malformation before surgery or radiation. In 15% to 25% of cases, glue embolization alone can result in complete angiographic obliteration of smaller AVMs. For deeply lying lesions not suitable for embolization or surgery, focused beam radiotherapy (radiosurgery) with a linear accelerator or Gamma Knife is an alternative therapy. Radiosurgery is most suitable for smaller (<3 cm) AVMs that are deeply situated and within eloquent brain tissue, making surgical resection more dangerous. Radiosurgery alone leads to complete obliteration of the AVM in approximately 65%, with permanent symptomatic radiation necrosis occurring of 2% to 4% and a subsequent annual AVM bleeding rate of 1.4%.

Complete eradication of an AVM using any combination of these techniques is documented with loss of any evidence of early venous filling during the arterial phase of angiography. Despite complete eradication documented by angiogram, a small number of lesions recur. At 1 year, the rate of AVM recurrence after complete surgical removal is approximately 3% in adults and 9% in children.

Outcome

Former estimates of morbidity and mortality from AVM hemorrhage have been revised downward. Widely cited annual rates of 4% per year documented in some publications applied predominantly in those with large, complex AVMs who have bled in the past and whose AVM was deemed too daunting for attempted removal. For 49% of those presenting with first hemorrhage at a large referral institution, their morbidity documented by the modified Rankin scale was 1 (no significant disability) and showed significantly better outcomes that those with primary brain hemorrhage not from AVM. Hemorrhages arising from venous aspect of the AVM into the ventricle may present with a spectacular-appearing hemohydrocephalus but experience a satisfactory outcome.

TABLE 42.1 Spetzler-Martin Grading Scale

	Grade
Size of Nidus	
Small (<3 cm)	1
Medium (3-6 cm)	2
Large (>6 cm)	3
Eloquence of Adjacent Brain	
Noneloquent	0
Eloquent[a]	1
Venous Drainage	
Superficial only	0
Deep	1

[a]Scores are used only to estimate the risk of surgical arteriovenous malformation resection. Scores range from 1 to 5. Score of 1 denotes low risk of surgical morbidity (approximately 5%). Arteriovenous malformations with a score of 5 are considered inoperable, with a surgical risk approaching 50% or more.

DURAL ARTERIOVENOUS FISTULAS

A dural arteriovenous fistula (dAVF) is an arteriovenous shunt located in the dural wall of the venous sinus or expanded layer of the dura mater. These shunts linking an arterial source directly to a dural sinus arise from a combination of factors: some traumatic, others from venous thrombosis, and some for reasons still not understood. They account for some 10% to 15% of intracranial vascular malformations.

Pathobiology

Thrombosis of a large vein or sinus may be the most common cause of dAVFs, occurring in more than half of cases. Current understanding is that the venous thrombosis creates a high enough resistance to normal arterial flow as to force creation of new pathways. Closed head injury with trauma to the brain surface or local spontaneous venous sinus thrombosis appears to recruit or enlarge the existing 90 μm arteriovenous shunts known to exist in the walls of the venous sinuses. The middle meningeal and other meningeal arteries are the most common sources of inflow, and the resulting fistula may be single or multiple. In some cases, the arterial inputs converge on a "shunted pouch," a bulging tubular or elliptic vascular structure that protrudes from a dural sinus. Once having developed, these fistulas presumably lose their capacity for autoregulation and progressively enlarge, recruiting arterial inflow and creating arterialized high-pressure flow in adjacent veins. The sites most affected are the transverse sigmoid sinus, tentorial, and anterior cranial fossa (including the cavernous sinus) and less often the spinal system or foramen magnum.

Clinical Features

dAVFs can reverse the blood flow of neighboring superficial and deep venous structures, including the dural sinuses and cortical and deep medullary veins, resulting in brain venous hypertension. Current classifications cite three types of dAVFs based on the type of venous drainage, presence of cortical venous reflux, and the number of fistulae. The Borden classification system (Table 42.2) assigns higher risk to the presence of retrograde cortical venous drainage and the development of local venous hypertension. Type I dAVFs, which drain anterograde into normal veins, usually have more benign clinical behavior. Type II and III dAVFs exhibit retrograde venous drainage into cortical veins in the subarachnoid space, which usually results from local thrombosis and occlusion of the adjacent dural venous sinuses. Type II and III dAVFs have a more aggressive natural history, with an increased risk of hemorrhage or of a nonhemorrhagic neurologic deficit. In one study, type II dAVFs were found to have aggressive behavior in 40% and type III in 80% of cases.

Hemorrhage is the presenting symptom of dAVF in 20%. Many other patients present with unusual syndromes of local brain edema, among them complex aphasia and visual disturbances.

TABLE 42.2 Borden Classification System for Dural Arteriovenous Fistulas[a]

Type I
• Drainage into meningeal veins, spinal epidural veins, or a dural venous sinus
• Normal anterograde flow in both the draining veins and other veins draining into the system
Type II
• Drainage into meningeal veins, spinal epidural veins, or a dural venous sinus
• Retrograde flow into the normal subarachnoid cortical veins
Type III
• Direct drainage into a dilated subarachnoid cortical veins or into an isolated segment of the venous sinus (which results from a thrombosis on either side of the dural sinus segment)
• Associated with local venous hypertension

[a]According to this classification, these lesions are further subclassified in type a (single-connection) or type b (multiple-connection) fistulas.

For fistulas affecting the cavernous sinus, the clinical spectrum is broad: A link to the venous system from a small arterial source may create diagnostic problems suggesting myasthenia gravis or ocular myopathy, less dramatic than the rapidly developing bulging erythematous eye in carotid-cavernous sinus fistula that was created by trauma.

Diagnosis

dAVFs are notoriously difficult to diagnose with a high degree of reliability by CT or magnetic resonance. For this reason, digital subtraction angiography is the gold standard for making the diagnosis. When diagnosed by angiogram (Fig. 42.3), there is usually early venous filling via the fistula into enlarged venous structures, with or without associated local venous sinus thrombosis. Those branches having access to a patent vein or sinus (meningeal and other dural arteries) can be dilated and convoluted to a degree seen in AVMs.

Management and Outcome

Treatment is by surgery or by transarterial or transvenous endovascular methods. The goal of treatment is complete obliteration of the fistula, correction of the venous shunting, and reversal of any cortical venous reflux. One of the most definitive means of treating dAVFs is to clip or embolize (using coils or liquid glue via the transvenous approach) a shunted pouch connecting the arterial inputs to a dural venous sinus. In a recent meta-analysis, surgery (sometimes preceded by embolization) was found to be associated with significantly lower odds of treatment failure and later recurrence compared to endovascular therapy alone. Neurologic improvement was also significantly higher after surgery compared with embolization alone. No difference in complication rates was observed between the two approaches. Persistence in efforts is often required, and repeated angiographic follow-up is mandatory because 10% to 15% of dAVFs recur even after

FIGURE 42.3 Images of a patient with a dural arteriovenous fistula (dAVF) involving the left transverse sinus. **A:** Three-dimensional computed tomography angiogram (view from top down) shows dilated veins on the left transverse sinus *(arrow)*. **B:** Angiogram of the left external carotid artery shows the dAVF; posterior division of the middle meningeal was the main feeding artery, and cortical venous reflux was observed. **C:** Angiogram of the vertebral artery showed that the posterior meningeal artery was also a feeding artery. **D:** The dAVF was embolized via the posterior division of the middle meningeal artery. (Reproduced with permission from Kirsch M, Liebig T, Kühne D, Henkes H. Endovascular management of dural arteriovenous fistulas of the transverse and sigmoid sinus in 150 patients. *Neuroradiology*. 2009;51:477-483.)

an angiographic cure. Interestingly, some reports document spontaneous regression of dAVF, and partial embolization can also lead to spontaneous resolution of the fistula later on. In one study of 150 transverse or sigmoid sinus dAVFs, the immediate angiographic cure rate after endovascular therapy was 54%. At follow-up, 88% of patients with some residual shunting after the treatment showed complete occlusion later on.

CAVERNOUS MALFORMATIONS

Cerebral cavernous malformations (CCMs) are also known as cavernomas, cavernous hemangiomas, and cavernous angiomas. Cavernous malformations are low flow, highly focal vascular anomalies; most of them are less than 1 cm in size. They may occur anywhere in the brain.

Pathobiology

The lesion is histologically characterized by grossly dilated vascular spaces (known as *caverns*) lined by a single layer of endothelium, lacking mature vessel wall angioarchitecture, and manifesting features of chronic hemorrhage in adjacent neuroglial parenchyma (Fig. 42.4). The gross appearance of the lesion has been likened to a mulberry.

In its sporadic form, CCMs occur as a solitary hemorrhagic vascular lesion, or as clustered lesions associated with a developmental venous anomaly. Multiple lesions—some numbering in the many dozens—have been documented in families. In its autosomal dominant familial form CCM caused by a heterozygous germline loss-of-function mutation in one of three genes—*CCM1/KRIT1*, *CCM2/Malcavernin*, and *CCM3/PDCD10*—that causes multifocal lesions throughout the brain and spinal cord. A founder mutation (Q455x) involving *KRIT1* and an associated preserved haplotype accounts for clustering of familial CCM disease in Hispanic Americans of Mexican descent and a common deletion in the *CCM2/Malcavernin* accounts for clustering among Ashkenazi Jews.

Diagnosis

The individual vessels and even the cluster are too small and low flow to be seen on angiogram and are rarely documented by CT scan but are easily seen on MRI (Fig. 42.5), thanks to the hemosiderin-iron composition from the slow flow through the lesion or from asymptomatic hemorrhages. The typical target lesions appear as rings and result from repeated microhemorrhages. Gradient recalled echo acquired (T2*) sequences reveal the "blooming" effect of hemosiderin, increasing the sensitivity of detection of CCMs. Although they may be mistaken for a vascular tumor on imaging, there is no displacement of the surrounding structure.

Clinical Features

Approximately two-thirds of cavernous malformations are diagnosed when patients with symptoms of hemorrhage, seizures, headaches, or vague neurologic symptoms occur. Symptoms tend

FIGURE 42.4 **A:** Artist's rendition of the mulberry-like cerebral cavernous malformation. **B:** Three-dimensional magnetic resonance imaging slab of a human lesion, T2 acquisition at 3 Tesla, highlighting the characteristic "popcorn appearance" of a CCM with a hemosiderin ring. **C:** Confocal immunofluorescence photomicrograph with staining (CD31, *green*) of endothelial cells lining the lesion's vascular spaces (caverns). Red blood cells (*red*) fill the caverns and extravasate beyond the "leaky" endothelium. **D:** Comparative image of normal brain capillaries. (Reproduced with permission from Awad IA, Polster SP. Cavernous angiomas: deconstructing a neurosurgical disease. *J Neurosurg*. 2019;131[1]:1-13.)

FIGURE 42.5 Magnetic resonance imaging features of cavernous malformations. **A:** Magnetic resonance imaging features of a solitary CCM at the floor of the fourth ventricle, clustered around a developmental venous malformation traversing the pons. **B:** Autosomal dominant familial multifocal CCMs, including punctate lesions on susceptibility weighted imaging (SWI), which are not seen on conventional (T2 and gradient recalled echo [GRE] weighted) sequences. to develop between the second and fifth decade of life. The risk of hemorrhage is 6% annually in patients who have already experienced a bleeding event, and the risk gradually goes down with time. The median interval from primary to a repeat hemorrhage is 8 months. The incidence of symptomatic hemorrhage or rehemorrhage is higher in brainstem lesions. The risk of bleeding in patients presenting with symptoms unrelated to hemorrhage is 2% annually. Of the one-third of patients who present with an incidentally discovered cavernous malformation, the bleeding risk is only 0.08% per year. However, once a symptomatic hemorrhage has occurred, the annual risk of a subsequent episode of bleeding is dramatically increased—at least 10-fold by most estimates. This elevated risk is greatest soon after a hemorrhage but persists thereafter, with a 5-year risk estimated at 40%. The risk of symptomatic rebleeding is higher with brainstem lesions, although this may reflect enhanced sensitivity due to the eloquence of these structures.

The bleeding events themselves tend to be low impact, compatible with gradual breakdown of the malformation and "oozing" of blood over period of hours, in contrast with the violent bleeding events that can occur with rupture of a lenticulostriate artery in the setting of hypertensive intracerebral hemorrhage (see Chapter 39). The clinical effects of hemorrhage are accordingly usually limited, often causing no or minimal symptoms. Serious deficits are generally restricted to patients with malformations in the brainstem.

Management

If hemorrhage has occurred and the lesion is readily accessible, surgery is usually recommended. Case series generally report low rates of surgical morbidity and mortality for supratentorial CCMs but much higher rates for brainstem lesions. Surgical complication rates, however, clearly exceed the low risks from hemorrhage in lesions that have never bled. Hence, surgical excision of asymptomatic lesions, particularly those lying deep or in brainstem locations, are almost never justified. On the other hand, the risk-benefit ratio with surgery appears to be beneficial when compared to the risk of recurrent hemorrhage from CCMs that have already bled. Stereotactic radiosurgery has been suggested as an alternative treatment for symptomatic CCMs located in eloquent areas, with most series identifying a decline in the hemorrhage rate more than 2 years after stereotactic radiosurgery treatment

VENOUS MALFORMATIONS

Venous malformations (also deep venous anomalies) have no apparent arterial supply. They are not an AVM, they are simply anomalous veins that form from normal arterial vessels and capillary beds (see Fig. 42.5, panel A). They may cause headaches, seizures, or, rarely, hemorrhage, but the vast majority are asymptomatic. They generally lie in the deep white matter and portions of the brainstem and cerebellum and often have spiderlike venous branches into the adjacent parenchyma (so-called caput medusa). They are easily recognized on MRI because of their contrast enhancement. Because they are so often asymptomatic and also serve as the venous draining system for the adjacent brain, they are not amenable to obliteration by occlusion of the arterial supply or surgical resection. They generally follow a benign course.

TELANGIECTASIAS

Telangiectasias are collections of engorged capillaries or cavernous spaces separated by relatively normal brain tissue. They are usually small and poorly circumscribed. Although found in any portion of the central nervous system, they have a propensity for the cerebral white matter. In the Rendu-Osler-Weber syndrome, brain telangiectasias are associated with similar lesions of the skin (mucous membranes, respiratory, gastrointestinal, and genitourinary tracts). Those occurring in the lung may provide a path for septic material for brain abscess formation. The fistulas are usually tiny, and some are not demonstrated despite angiography. Major hemorrhage is rare. Interest in genetic mapping for the remarkable variety of telangiectasias has increased greatly and may well lead to a total reclassification of these lesions separate from the classical clinical description.

Sturge-Weber Disease

The main features of this rare disorder, also known as *Krabbe-Weber-Dimitri disease*, are localized atrophy and calcification of the cerebral cortex associated with capillary and venous malformations. Any portion of the cerebral cortex may be affected by the atrophic process, but the occipital and parietal regions are most commonly involved. Usually, also present is an ipsilateral port-wine–colored facial nevus, usually in the distribution of the first division of the trigeminal nerve. Included among the clinical features may be angiomatous malformations in the meninges, ipsilateral exophthalmos, glaucoma, buphthalmos, angiomas of the retina, optic atrophy, and dilated vessels in the sclera.

In the atrophic cortical areas, there is a loss of nerve cells and axons and a proliferation of the fibrous glia. The small vessels are thickened and calcified, particularly in the second and third cortical layers. Small calcium deposits are also present in the cerebral substance, and rarely, there are large calcified nodules. When an angioma is present, it is limited to the meninges overlying the area of shrunken cortex. Although the combination of a port-wine facial nevus and localized cortical atrophy may exist without clinical symptoms, convulsive seizures are usually present from infancy. Developmental delay, glaucoma, contralateral hemiplegia, and hemianopia are also present in most cases.

Sturge-Weber disease can be diagnosed without difficulty from the clinical syndrome. The presence of the cortical lesion can be demonstrated in most cases by the appearance of characteristic shadows in the radiographs. The treatment of Sturge-Weber disease is essentially symptomatic. Anticonvulsive drugs are given for the seizures. Radiation therapy has been recommended, but there is no evidence that it is of any benefit.

Sinus Pericranii

The disorder is a combination of thin-walled vascular spaces interconnected by numerous anastomoses that protrude from the skull and communicate with the superior longitudinal sinus. The malformation is usually evident in infancy, soft and compressible; it increases in size when the venous pressure in the head is raised by coughing, straining, or lowering the head. It may enlarge slowly over a period of years. The external protuberance may be seen at any portion of the midline of the skull, including the occiput, but is most often found in the midportion of the forehead. Imaging shows a defect of the underlying bone, through which the lesion communicates with the longitudinal sinus.

VASCULAR TUMORS

These three forms of neoplastic lesions may be variations of the same tumor. Histologically, they are indistinguishable but share similar clinical features.

Hemangioblastomas

Hemangioblastomas are composed of primitive vascular elements and are rare, accounting for 1% to 2% of all intracranial neoplasms. They occur at all ages, but young and middle-aged adults are more frequently afflicted. In children, they are almost as common in the posterior fossa as are meningiomas. Symptoms are generally present for approximately a year before the diagnosis is made. Male incidence predominates. Von Hippel-Lindau disease is defined by the coexistence of hemangioblastoma and multiple angiomatoses of the retina, cysts of the kidney and pancreas, and, occasionally, renal cell carcinomas, and capillary nevi of the skin. There is a familial incidence in 20% of cases. Only 10% to 20% of the hemangioblastomas, however, are associated with the systemic signs known as the *Lindau syndrome*. All gradations of clinical expression between the full syndrome and incomplete manifestations may be seen in the same family. Associated with these disorders are pheochromocytoma, syringomyelia, and polycythemia (which disappear after resection of the neoplasm but returns with recurrence).

Hemangioblastomas occur predominantly in the cerebellum and are often associated with large cysts that are surrounded by a glial wall containing yellow proteinaceous fluid, the result of secretion, and hemorrhage from the tumor. It resembles the cyst and mural nodule of the cystic cerebellar astrocytoma but has a distinctive vascular appearance on an angiogram. They may be multiple, in which case difficulty in achieving a cure or total removal of the lesion may be encountered. They have no dural attachment.

Hemangioblastoma can also occur in the spinal cord or in the medulla in the area postrema. They rarely occur in the supratentorial area, where they may be confused with angioblastic meningiomas.

Clinical features of the hemangioblastoma of the cerebellum are symptoms typical of any cerebellar mass, such as headache, papilledema, and ataxia. When the tumor is multiple, lesions may involve the brainstem and upper cervical cord as well. Spinal cord hemangioblastomas are often associated with syrinx formation. Hemangioblastoma of the cerebellum can be diagnosed without difficulty with MRI and magnetic resonance angiography. The diagnosis is even more certain when the tumor is associated with angiomas of the retina and polycythemia. Treatment is surgical, with evacuation of the cyst and removal of the mural nodule; 85% of all patients who undergo this treatment are alive and well 5 to 20 years after surgery. There is a high incidence of recurrence, however, if the tumor is partially removed or is associated with multiple tumors.

Angioblastic Meningioma and Hemangiopericytoma

Angioblastic meningioma is grossly identical to other meningiomas but has a significant dural attachment and is located either above or below the tentorium. Hemangiopericytoma originates in other areas of the body, presumably from blood vessel elements.

Central Nervous System Vasculitis 43

Kavneet Kaur, Hussein Alshammari, Ramandeep Sahni, Steven Marks, Stephan A. Mayer, and Fawaz Al-Mufti

KEY POINTS

1. The gold standard for diagnosis of primary angiitis of the central nervous system (PACNS) is tissue biopsy.
2. Systemic vasculitis is more common than primary central nervous system vasculitis.
3. For the majority of systemic vasculitis, treatment with glucocorticoids and cyclophosphamide for induction therapy and maintenance therapy with azathioprine have improved outcome and mortality rates.
4. Clinical suspicion of giant cell arteritis should prompt early initiation of high-dose steroids without waiting for biopsy to delay treatment.
5. Polyarteritis nodosa is associated with hepatitis B virus but association with hepatitis C virus, cytomegalovirus, and parvovirus B19 has been reported.
6. Catheter angiography findings of reversible cerebral vasoconstriction syndrome are indistinguishable from PACNS and is the most common mimicker of PACNS.
7. Reversible cerebral vasoconstriction syndrome is self-limited and more benign than PACNS.

INTRODUCTION

Vasculitis affecting the central nervous system (CNS) or peripheral nervous system often presents major diagnostic and therapeutic challenges for physicians because of its variable clinical manifestations and the lack of specific diagnostic tests other than biopsy. The CNS vasculitis comprises a heterogeneous group of inflammatory diseases that affect leptomeningeal and parenchymal blood vessels of the brain with different but frequently overlapping clinical and pathologic manifestations.

The histopathologic changes of CNS vasculitis essentially consist of an inflammatory infiltrate within the vessel wall associated with necrosis, vessel occlusion and infarction, and occasionally hemorrhage. The cases of CNS vasculitis are protean: It may occur as an idiopathic primary autoimmune process or within the context of systemic to autoimmune disease, as a reaction to an infection such as varicella-zoster or a neurodegenerative process such as amyloid angiopathy, after drug exposure (eg, cocaine), as a manifestation of radiation exposure, and in the setting of malignancy. Although the precise pathogenesis often remains obscure, in all cases, the immune system plays a central role, and immunosuppressive agents are the cornerstones of treatment.

There are several different classifications for CNS vasculitis. Some classifications are based on the size of the affected vessels (small, medium, large), whereas other classifications are based on histologic features (eg, granulomatous, lymphomatous, or leukocytoclastic inflammation) or immunologic markers (eg, the association with antineutrophil cytoplasmic antibodies [ANCAs] with some forms of vasculitis). The CNS vasculitis can also be further broadly classified into primary and secondary vasculitis depending on whether the process is confined to the CNS or is part of a systemic illness.

In 2012, the International Chapel Hill Consensus Conference proposed a revised nomenclature system that groups different vasculitides by taking in consideration multiple factors including size of vessels and whether the vasculitis involves a single organ or is part of a more systemic condition (Table 43.1 and Fig. 43.1).

PRIMARY ANGIITIS OF THE CENTRAL NERVOUS SYSTEM

Primary angiitis of the central nervous system (PACNS) is associated with select inflammation and destruction of small- and medium-sized arteries of the brain parenchyma, spinal cord, and leptomeninges, resulting in symptoms and signs of CNS dysfunction. The term *angiitis* is synonymous with vasculitis and refers to involvement of blood vessels on both the arterial and venous sides of the circulation. The PACNS is also frequently referred to as *primary central nervous system vasculitis*.

Epidemiology

The annual incidence rate of PACNS is 2.4 cases per 1 million person-years. The disease affects patients of all ages, peaking at 50 years of age, with a 2:1 male predominance.

Pathobiology

The etiology and pathogenesis of PACNS is unknown. Infectious agents such as herpes zoster virus, West Nile virus, and varicella-zoster virus have been proposed as possible causes or triggers.

Three main histopathologic patterns are generally seen: granulomatous, lymphocytic, and necrotizing vasculitis. In lymphocytic PACNS, immunohistochemical staining reveals predominant infiltration by memory T cells in and around small cerebral vessels, signifying an antigen-specific immune response occurring in the wall of cerebral arteries.

Clinical Features

Due to diffuse involvement of the CNS, the clinical manifestations are variable and nonspecific, with a clinical course rang-

TABLE 43.1 Vasculitis Syndromes: 2012 International Chapel Hill Consensus Conference[a]

Syndromes	Pathologies
3.1 Large-Vessel Vasculitis	
3.1.1 Giant cell (temporal) arteritis	Granulomatous arteritis of aorta and its major branches; predilection for extracranial branches of carotid artery; often involves temporal artery; patients older than 50 years with polymyalgia rheumatica
3.1.2 Takayasu arteritis	Granulomatous arteritis of aorta and major branches; patients younger than age 50 years
3.2 Medium-Sized Vessel Vasculitis	
3.2.1 Polyarteritis nodosa	Necrotizing inflammation of medium- or small-sized arteries; no glomerulonephritis or vasculitis of arterioles, capillaries, venules
3.2.2 Kawasaki disease	Arteritis of large, medium-sized, small arteries plus mucocutaneous-lymph node syndrome; coronary arteries often involved; aorta and veins may be involved; usually in children
3.3 Small-Vessel Vasculitis	
3.3.1 Granulomatosis with polyangiitis (Wegener granulomatosis)	Granulomatous inflammation including respiratory tract and necrotizing vasculitis of small to medium vessels (capillaries, venules, arterioles, arteries); necrotizing glomerulonephritis common
3.3.2 Eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome)	Eosinophil-rich granulomatous inflammation of respiratory tract and necrotizing vasculitis of small- to medium-sized vessels; with asthma and eosinophilia
3.3.3 Microscopic polyangiitis	Necrotizing vasculitis with few or no immune deposits; affects small vessels (capillaries, venules, arterioles); may involve small- and medium-sized arteries; common features: necrotizing glomerulonephritis and involvement of pulmonary capillaries
3.3.4 IgA vasculitis (Henoch-Schönlein purpura)	Vasculitis with IgA-dominant immune deposits on small vessels (capillaries, venules, arterioles); affects skin, gut, and glomeruli plus arthritis or arthralgia
3.3.5 Cryoglobulinemic vasculitis	Vasculitis with immune deposits on small vessels (capillaries, venules, arterioles); cryoglobulins in serum; skin and glomeruli often involved
3.4 Variable-Vessel Vasculitis	
3.4.1 Behçet disease	Vasculitis that can affect arteries or veins accompanied by cutaneous, ocular, articular, gastrointestinal, and/or central nervous system inflammatory lesions
3.4.2 Cogan syndrome	Arteritis (affecting small, medium, or large arteries), aortitis, aortic aneurysms, and aortic and mitral valvulitis accompanied by ocular inflammatory lesions, including interstitial keratitis, uveitis, and episcleritis, and inner ear disease, including sensorineural hearing loss and vestibular dysfunction
3.4.3 Vasculitis associated with systemic disease	Vasculitis that is associated with and may be secondary to (caused by) a systemic disease (eg, rheumatoid vasculitis, lupus vasculitis)
3.4.4 Vasculitis associated with probable etiology	Vasculitis that is associated with a probable specific etiology (eg, hydralazine-associated microscopic polyangiitis, hepatitis B virus–associated vasculitis, hepatitis C virus–associated cryoglobulinemic vasculitis)

Abbreviation: IgA, immunoglobulin A.
[a]Modified from Jennette JC, Falk RJ, Bacon PA, et al. 2012 revised International Chapel Hill Consensus Conference nomenclature of vasculitides. *Arthritis Rheum.* 2013;65(1):1–11.

ing from hyperacute to stepwise to chronic and insidious. Mental obtundation and decreased cognition are the most frequent clinical presentations, usually evolving subacutely as a progressive encephalopathy. Other symptoms may include headaches, seizures, and focal neurologic deficits due to ischemic stroke or cerebral hemorrhage. Signs and symptoms of systemic vasculitis, such as peripheral neuropathy, fever, weight loss, or rash, are by definition lacking in PACNS.

Diagnosis

On the basis of clinical experience and evidence from published work, Calabrese and Mallek proposed a set of criteria for the diagnosis of PACNS; the diagnosis is established when all three of the following criteria are met (Table 43.2).

Laboratory Findings

There is no specific laboratory diagnostic test for PACNS, although routine laboratory testing, serologic evaluations, lumbar puncture results, neuroimaging studies, cerebral angiography, and brain biopsy may all have roles in the evaluation (Table 43.3). Acute phase reactants such as the erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are normal or slightly elevated in PACNS; elevated levels should raise suspicion of systemic involvement by either an infectious, malignant, or inflammatory process. Both serologic testing and analyses of the cerebrospinal fluid (CSF) are important for excluding secondary causes of CNS dysfunction that may mimic PACNS. Nonspecific abnormalities, primarily leukocyte and protein elevations, are seen on CSF analysis in 80% to 90% of patients with pathologically documented disease.

Imaging

Magnetic resonance imaging (MRI) typically shows multifocal small-vessel infarcts and hemorrhages of varying age (Fig. 43.2). These vascular lesions often involve structures that are not typically involved in conventional cerebrovascular disease, such as the corpus callosum. In some cases, large-vessel infarcts, convexity subarachnoid hemorrhage, or small foci of gadolinium

FIGURE 43.1 Classification of CNS vascultis, which takes into account primary CNS versus systemic involvement and the size of the involved vessels.

enhancement can occur. It is extremely rare for PACNS to cause advanced disease with severe symptoms with a normal MRI.

The gold standard for the detection of vascular abnormalities is tissue biopsy. In PACNS, cerebral angiography may show multiple segmental areas of ectasia, dilation or stenosis referred to as *beading*: circumferential or eccentric vessel irregularities with sharp cutoffs, delayed arterial emptying, small arteriovenous anastomotic channels, and rarely, microaneurysms (Fig. 43.3). The main condition that PACNS must be differentiated from a patient with beading on diagnostic angiography is reversible cerebral vasoconstriction syndrome (RCVS), a much more benign condition discussed later in this chapter (see also Chapter 44). About 4% of patients with primary CNS vasculitis present with a solitary tumorlike mass lesion due to brain tissue inflammation. Given the poor resolution of computed tomography and magnetic resonance angiography for distal medium and small blood vessels, these tests have limited specificity for diagnosing PACNS.

Arteries with diameter below 0.4 mm, arterioles, and capillaries are beyond the resolution of conventional angiography, and because PACNS often involves small blood vessels, the sensitivity of angiography in biopsy-proven PACNS cases is only 60%. Thus, a negative angiogram cannot exclude the diagnosis of PACNS. Furthermore, cerebral angiography has limited specificity because not infrequently, patients with angiographic findings interpreted as being positive for vasculitis are not found to have vasculitic changes at brain biopsy. It should be noted that normal biopsy specimens may reflect sample error due to the patchy distribution of inflammation. The false-negative rate of an initial biopsy is 25%; in some cases, two or more biopsies are necessary to establish the diagnosis. The yield of biopsy is improved with larger tissue blocks (ie, 1 cm^3) with inclusion of the overlying meninges and when areas affected with enhancement on MRI are targeted.

TABLE 43.2 Diagnostic Criteria for Primary Angiitis of the Central Nervous System

- History or clinical findings of an acquired neurologic deficit of unknown origin after a thorough initial basic assessment
- Cerebral angiography reveals classic features of vasculitis, or a CNS biopsy sample shows vasculitis.
- There is no evidence of systemic vasculitis or any other disorder to which the angiographic or pathologic features can be attributed to.

Abbreviation: CNS, central nervous system.

Management

No randomized clinical trials of medical management for PACNS exist. First-line therapy usually starts with glucocorticoids. Fulminant PACNS in hospitalized patients usually starts with empiric intravenous *methylprednisolone*, 15 mg/kg/d for 3 to 5 days, followed by *prednisone*, 1 mg/kg/d to a maximum of 100 mg/d. Less severe disease in outpatients can be started on *prednisone* alone. Glucocorticoids should be continued at the initial dose for 4 to 6 weeks after which a slow taper should be initiated.

Patients with biopsy-confirmed granulomatous variant PACNS should be started on a combination of glucocorticoids and *cyclophosphamide*. *Cyclophosphamide* is given in order to induce remission in either a daily oral regimen (1.5-2 mg/kg/d) or a monthly intravenous regimen (600-750 mg/m^2, infused once a month). After induction of remission, typically in 3 to 6 months, *cyclophosphamide* therapy is switched to maintenance therapy with other agents such as mycophenolate mofetil or azathioprine.

TABLE 43.3 Suggested Laboratory Testing for Central Nervous System Vasculitis

Complete blood count with differential
Serum urea nitrogen and creatinine
Serum aspartate and alanine aminotransferases
ESR and C-reactive protein
Urinalysis
CSF Studies
Cell count (mild to moderate CSF pleocytosis expected)
CSF protein (elevated to 1,034 mg/dL reported) CSF glucose (usually normal)
Oligoclonal bands
Gram stain and cultures
Cytology and flow cytometry to rule-out malignancy
PCR and IgG, IgM directed at infectious sources (below)
Specialized Laboratory Testing
Antinuclear antibodies
Rheumatoid factor
Antibodies to the Ro/SSA, La/SSB, Sm, and RNP antigens
Antibodies to double-stranded DNA
Antineutrophil cytoplasmic antibodies (ANCA)
Serum C3 and C4
Serum cryoglobulins
Serum and urine protein electrophoresis with immune electrophoresis
Quantitative immunoglobulin levels (IgG, IgM, IgA)
Infectious Etiologies (In Appropriate Circumstances as Indicated)
Bacterial—*Mycoplasma* PCR and serology, antistreptolysin O test, syphilis serology, Mantoux skin test
Viral—serology for hepatitis B and C, parvovirus B19, HIV, herpes simplex virus, Epstein-Barr virus, cytomegalovirus, varicella
Fungal culture (*Aspergillus*, *Coccidioides*, and *Histoplasma* species)
Parasite: serum anticysticercal antibodies demonstrated by immunoblot assay and CSF ELISA for detection of anticysticercal antibodies or cysticercal antigens
Thrombophilia Investigations
Prolonged activated partial thromboplastin time, which does not correct with mixing
Screening for lupus anticoagulant
Anticardiolipin antibody by ELISA
Anti-β_2-microglobulin-1 antibody by ELISA

Abbreviations: CSF, cerebrospinal fluid; ELISA, enzyme-linked immunosorbent assay; ESR, erythrocyte sedimentation rate; HIV, human immunodeficiency virus; IgA, immunoglobulin A; IgG, immunoglobulin G; IgM, immunoglobulin M; PCR, polymerase chain reaction; RNP, ribonucleoprotein; Ro/SSA, Anti-Sjögren's-syndrome-related antigen A (also called anti-Ro); Sm, Smith.

FIGURE 43.2 Fluid-attenuated inversion recovery magnetic resonance imaging showing multifocal infarcts in a patient with biopsy-proven primary angiitis of the central nervous system.

FIGURE 43.3 Typical angiographic findings in a patient with central nervous system vasculitis. *Arrows* point to areas of alternating stenosis and ectasia. (From Hajj-Ali RA, Ghamande S, Calabrese LH, Arroliga AC. Central nervous system vasculitis in the intensive care unit. *Crit Care Clin*. 2002;18:897-914.)

In patients with lymphocytic variant PACNS or those in whom the diagnosis is performed by cerebral angiogram and not confirmed by biopsy, an initial glucocorticoid treatment is only followed by *cyclophosphamide* if the neurologic decline is progressive. As a general rule, chemotherapeutic immunosuppressant therapy should only be given to patients with biopsy-proven PACNS.

Treatment response is monitored by periodic reassessment of symptoms and neuroimaging abnormalities. A follow-up MRI

should be obtained 4 to 6 weeks after beginning treatment, then every 3 to 6 months throughout therapy, and subsequently according to the evolution of the disease to assess for progression of the disease.

Outcome

Earlier descriptions characterized PACNS as a fatal disease, and most cases were diagnosed at autopsy. With better understanding of the disease and with aggressive immunosuppression, more favorable outcomes and improving mortality rate have been reported. Recent reports indicate that the short-term mortality rate is 10% and that 20% suffer severe functional impairment. Mild cognitive deficits and reduced energy level remain common among those with a good functional recovery. Approximately 30% of patients experience a relapse of the disease after going into remission, which requires reescalation of immunosuppression.

AMYLOID β–RELATED ANGIITIS

Amyloid β–related angiitis (ABRA) is a rare form of CNS vasculitis in which perivascular β–amyloid is thought to act as a trigger for inflammation mediated by $CD68^+$ 1macrophages and $CD3^+$ T lymphocytes. The condition develops in patients with symptomatic or asymptomatic amyloid angiopathy (see Chapter 39), which presents as dementia, gait disorder, and progressive brain hemorrhages (both microbleeds and parenchymal intracerebral hemorrhage). Patients with amyloid β–related angiitis often exhibit altered mental status and respond to immunosuppressive treatment. Common CSF findings include an elevated protein and a lymphocytic pleocytosis. The MRI often demonstrates T2 hyperintense lesions extending through the cortical white matter and often gray matter, suggestive of breakdown of the blood-brain barrier and a reversible leukoencephalopathy. Cerebral angiography shows beading in a minority of patients, perhaps due to involvement of exclusively medium- and small-sized vessels. In every case on brain biopsy, microglia, macrophages, and T cells surround amyloid-laden vessels. After initiating anti-inflammatory treatment consisting of *steroids* followed by *cyclophosphamide* for a duration ranging from 2 weeks to several months, a majority of patients with amyloid β–related angiitis show improvement. However, some patients relapse, and other patients do not improve or progressively decline.

CENTRAL NERVOUS SYSTEM VASCULITIS ASSOCIATED WITH SYSTEMIC VASCULITIS

Large-Vessel Vasculitis

Giant Cell (Temporal) Arteritis

Giant cell arteritis (GCA), also known as *temporal arteritis* because of its predilection for superficial temporal artery involvement, is a large-vessel granulomatous vasculitis. The disease usually affects the aorta or its major branches, with a predilection for the branches of the cervical internal and external carotid arteries and the vertebral arteries. The intracranial vessels are generally spared. The GCA is often linked with polymyalgia rheumatica in terms of its systemic manifestations, ESR elevation, and response to steroid therapy.

Epidemiology

The GCA has an annual incidence that is highest among white individuals, ranging between 10 and 20 cases per 100,000 among persons older than 50 years of age. The incidence is markedly lower in persons of Asian or African descent in the range of 1 case per 100,000. Although GCA almost never occurs before age 50 years, the incidence increases thereafter, reaching its peak incidence between the ages of 70 and 80 years.

Pathobiology

Although the etiology of GCA is unknown, there appears to be an interplay between increasing age, a genetic predisposition, and infectious triggers that involves both the cellular and humoral immune system, resulting in an acute vascular inflammatory state. Current literature regarding the molecular basis of GCA suggests that activated dendritic cells, residing in the vessel wall, play an important role in the pathophysiology by initiating the pathogenic cascade, recruiting T cells and macrophages to form granulomatous infiltrates.

GCA is a panarteritis, including all the arterial layers. Thrombosis may develop at sites of active inflammation. Fibrosis, scarring, and narrowing or occlusion of the arteries develops secondary to the inflammation, tissue injury, and repair process.

Clinical Manifestations

GCA is classically characterized by a combination of five features:

- Age older than 50 years
- A localized new-onset headache
- Tenderness over the temporal artery
- An elevated ESR (>50 mm/h)

Biopsy revealing a necrotizing arteritis with a predominance of mononuclear cells or a granulomatous process with multinucleated giant cells is classically characterized by a combination of five features:

1. Age older than 50 years
2. A localized new-onset headache
3. Tenderness over the temporal artery
4. An elevated ESR (>50 mm/h)
5. Biopsy revealing a necrotizing arteritis with a predominance of mononuclear cells or a granulomatous process with multinucleated giant cells

The presence of three of the above five criteria is associated with 94% sensitivity and 91% specificity for the diagnosis of GCA. The GCA typically presents with a constellation of constitutional symptoms, headache and tenderness over the temporal artery, jaw claudication, visual symptoms, and symptoms of polymyalgia rheumatica (diffuse myalgias and body aches). Because intracranial vascular involvement is rare in GCA, transient ischemic attacks (TIAs) and stroke are usually secondary to embolism or flow failure related to cervical vertebral or internal carotid lesions.

Neurologic manifestations arise in approximately 30% of patients, with more than half being peripheral neuropathies, followed by one-third with TIA or stroke, one-third with ophthalmologic symptoms, and one-fifth with neuro-otologic syndromes. Ophthalmologic symptoms can include transient monocular blindness (ie, retinal TIA or amaurosis fugax) due to

internal carotid artery stenosis or sustained unilateral visual loss due to anterior ischemic optic neuropathy or occlusion of the central retinal artery (see Chapter 10).

Diagnosis

Tests to rule out CNS vasculitis should be performed as delineated in **Table 43.3**. The classic diagnostic screening test is an ESR, which is elevated in nearly all patients. The CRP levels are also elevated, and CRP tends to correlate more than ESR with GCA disease activity. Interleukin-6 levels have been used to evaluate disease progression, although this is investigational at this point.

Temporal artery biopsy, evidencing vasculitis with predominance of mononuclear cell infiltration or granulomatous inflammation, usually with multinucleated giant cells, is the gold standard for the diagnosis of GCA. A negative initial temporal artery biopsy may be present and occurs in up to 40% of patients with suspected of GCA. This may be due to sampling error due to skip lesions, biopsy, or attainment of too small a specimen (<2 cm). In the presence of a high index of suspicion, a contralateral biopsy should be performed if the first biopsy is negative. If bilateral temporal artery biopsies are negative, alternate artery biopsy sites should be considered.

Management

Treatment recommendations for GCA are based on clinical experience rather than the results of randomized controlled trials with most cases being managed effectively with glucocorticoid monotherapy. Induction therapy with *prednisone* at a dose of 1 mg/kg of body weight per day (maximum of 60 mg/d) is initiated in patients who lack symptoms or signs of ischemic organ damage (eg, visual loss).

Patients with signs and symptoms suggestive of compromised blood flow to the eyes or the CNS should be managed with *methylprednisolone* at a dose of 1,000 mg/d for 3 consecutive days to more rapidly induce immunosuppression. This is then followed by oral therapy with 1 mg/kg of body weight per day (maximum of 60 mg/d) as recommended earlier for uncomplicated GCA. Once tissue necrosis occurs (eg, optic nerve ischemia with blindness for several hours), it is irreversible.

Treatment initiation for suspected GCA with neurologic involvement should never be delayed until the biopsy is obtained because resolution of the inflammation occurs slowly after the start of treatment, and a confirmed pathologic diagnosis can take several weeks or even months to attain.

Despite lack of prospective trials, anecdotal reports suggest some beneficial effects with glucocorticoid-sparing therapies such as *methotrexate*, *cyclophosphamide*, and *tocilizumab* (interleukin-6 receptor antagonist). These therapies may be considered in patients at highest risk for experiencing glucocorticoid-related side effects.

Once clinical signs have subsided and laboratory values have normalized, steroids can be tapered by 10 mg/kg every 2 to 4 weeks, with a substantial slowing of the taper to 1 mg decrements per month once the daily dose of 10 mg is reached. Expert consensus also recommends the addition of *acetylsalicylic* acid (75-50 mg/d) to reduce the risk of ischemic complications such as visual loss, TIAs, or stroke.

Outcome

GCA tends to run a self-limited course over several months to several years. Rapid clinical improvement following the initiation of treatment is typical. The glucocorticoid dose can eventually be reduced or discontinued with the average duration of treatment being 2 to 3 years. Fatalities are rare.

Takayasu Vasculitis

Also, known as *pulseless disease*. This large vessel vasculitis is a chronic granulomatous inflammatory process in which neurologic involvement is not very common but has been reported. It usually affects middle-aged women of Asian descent. Usually, it affects large vessels commonly aorta and its major branches including the subclavian, carotids, and vertebral arteries. Neurologic manifestations are secondary to vessel occlusion, stenosis, dilatation, or aneurysm formation that may lead to TIA, stroke, and hypertensive encephalopathy. Treatment is usually with glucocorticoids.

Medium-Vessel Vasculitis

Polyarteritis Nodosa

Polyarteritis nodosa (PAN) is a systemic necrotizing small- and medium-sized arteritis sparing the arterioles, capillaries, and venules. The ANCAs are typically negative in PAN; this is important in differentiating it from ANCA-associated vasculitis, which can present almost indistinguishably, both clinically and pathologically.

Epidemiology

PAN is a rare disease occurring in two per million people, with about 25% of cases involving the CNS. Men and women are affected equally. The disease may occur at any age, but the peak incidence is in the fourth to sixth decades of life. With the advent of hepatitis B vaccination, the incidence of hepatitis B virus (HBV)-associated PAN is declining.

Pathobiology

The etiology of PAN remains unknown; immune complex deposition, antigen-specific T-cell–mediated immune responses and reactions to bacterial or viral infection have been postulated. Hepatitis B has been identified as one of the most common triggers for a subset of PAN; this form of arteritis may be monophasic with a good prognosis. The PAN has also been reported with hepatitis C virus (HCV), cytomegalovirus, human immunodeficiency virus, and parvovirus B19.

Vascular inflammatory lesions in PAN are segmental and predominate in branching points of small- and medium-sized arteries. Small vessels, including arterioles, capillaries, and venules, are characteristically spared, as are large vessels (the aorta and its major branches). Consequently, glomerulonephritis is not part of the spectrum of PAN. Vessel inflammation starts in the adventitia and vasa vasorum may subsequently progress to include the entire arterial wall, resulting in fibrinoid necrosis. At bifurcations and branch points, multiple small aneurysms can form, and at later stages, angiogenesis becomes apparent. As these lesions progress, they may rupture or occlude the vessel, resulting in hemorrhage or infarction. Vessel biopsies typically show acute necrotizing lesions intermixed with more chronic fibrotic or healing changes, representing different stages of the inflammatory process.

Clinical Manifestations

The ubiquitous nature of PAN allows for the diverse clinical manifestations, ranging from more chronic, insidious symptoms to acute, life-threatening complications. Nonspecific constitutional manifestations are common early in the course.

Peripheral neuropathy, in the form of mononeuritis multiplex or diffuse sensorimotor peripheral neuropathy, is the most common neurologic disorder. Involvement of the CNS occurs in fewer than 10% of patients with PAN. The CNS manifestations range from headache, retinopathy, and encephalopathy with seizures and cognitive decline to cerebral infarction and intracerebral hemorrhage due to involvement of medium-sized vessels. Other symptoms may arise from affection of the cranial nerves or the spinal cord.

Cutaneous hemorrhages, tender erythematous eruptions, subcutaneous nodules, and necrotic ulcers may appear on the trunk or limbs. Variable degrees of renal insufficiency and hypertension may develop secondary to tissue infarction and hematoma formation secondary to rupture of renal microaneurysms. Furthermore, gastrointestinal, hepatic, testicular, or cardiac symptoms may develop.

Diagnosis

The diagnosis of PAN should be considered in all patients with an obscure febrile illness marked by systemic symptoms and chronic peripheral neuropathy. According to the American College of Rheumatology 1990 consensus criteria for the classification of PAN, the diagnosis is 82% sensitive and 87% specific in a patient with systemic vasculitis if there are more than 3 of the following 10 criteria: weight loss (≥4 kg), livedo reticularis, testicular pain or tenderness, myalgia, mononeuritis multiplex or other polyneuropathy, hypertension, azotemia, HBV antibody, angiographic occlusion of visceral arteries, or biopsy evidence of granulocytes in vessel wall.

Laboratory

The diagnosis can often be established by biopsy of sural nerve, muscle, or testicle. A high index of suspicion is crucial to diagnose PAN. Basic laboratory tests, liver function studies, and hepatitis (HBV and HCV) serologies help rule out potential etiologies and ascertain the extent of organs affected and their degree of involvement. Acute-phase proteins are typically elevated. There is a leukocytosis with inconstant eosinophilia. Additional specialized autoimmune laboratory testing is valuable in narrowing the differential diagnosis (see **Table 43.3**). The presence of myeloperoxidase (MPO) ANCA or proteinase 3 (PR3) ANCA antibodies strongly argues against PAN and in favor of one of the ANCA-associated vasculitides.

Management

There is no specific therapy. Treatment varies according to the severity of the disease state ranging from high doses of corticosteroids in milder disease forms to a combination of corticosteroids and immunosuppressive drugs (*azathioprine*, *methotrexate*, or *cyclophosphamide*). Patients with mild PAN and evidence of infection with HBV or HCV should receive antivirals, whereas those with severe hepatitis virus–associated PAN, short-term treatment corticosteroids, and plasma exchange maybe considered until antiviral therapy becomes effective. Plasma exchange may have a role in the acute management of HBV-associated PAN.

Outcome

Untreated PAN is associated with a poor prognosis. The French Vasculitis Study Group described the 1- and 5-year relapse rates for patients with non–HBV-associated PAN as 9.2% and 24%, respectively; the relapse rates for HBV-associated PAN were lower. Most deaths occur within 18 months of disease onset primarily due to renal failure and mesenteric, cardiac, or cerebral infarctions.

Kawasaki Disease

Kawasaki disease, also known as *Kawasaki syndrome*, previously called mucocutaneous lymph node syndrome, is one of the most common vasculitides of childhood. The affected patient population is children younger than 5 years old, but Kawasaki disease also occurs rarely in adults. Higher prevalence is seen in Japan. Clinical manifestations include long-standing fever, sore throat, diarrhea, lymphadenopathy, genital rash, red eyes, lips, palm, or soles. Complications include coronary artery vasculitis (50%) and CNS involvement (30%). Neurologic manifestations vary and can include cerebral hypoperfusion, stroke, subdural effusion, seizures, and coma. Unless it is contraindicated, all published guidelines include aspirin with intravenous immunoglobulin as initial treatment of Kawasaki disease.

Small-Vessel Vasculitis

The Antineutrophil Cytoplasmic Antibody–Positive Vasculitides

The ANCA vasculitis is a group of necrotizing small-vessel vasculitides predominantly affecting small vessels (ie, capillaries, venules, arterioles, and small arteries). The ANCA antibodies (usually immunoglobulin G) react against antigens in the cytoplasm of neutrophil granulocytes. Specific subtypes of ANCA are based on immunofluorescence patterns and target antigens. Cytoplasmic antineutrophil cytoplasmic antibody is directed specifically at PR3. Perinuclear antineutrophil cytoplasmic antibody antigens include MPO and bacterial permeability increasing factor.

The ANCA-associated vasculitides include the following:

1. Granulomatosis with polyangiitis (formerly known as *Wegener granulomatosis*)
2. Microscopic polyangiitis (MPA)
3. Eosinophilic granulomatosis with polyangiitis (formerly *Churg-Strauss syndrome*)
4. Renal-limited vasculitis
5. Drug-induced vasculitis

All are associated with ANCAs and a focal necrotizing, often crescentic, pauci-immune glomerulonephritis. The presence or absence of ANCA antibodies does not indicate presence or absence of disease. The ANCA is highly correlated with the conditions described in the following sections, but not all patients with the condition test positive for the antibody. The association of ANCA positivity and disease activity remains controversial; however, the reappearance of ANCA after treatment can indicate a relapse.

Granulomatosis With Polyangiitis

Introduction

The hallmarks of granulomatosis with polyangiitis (GPA), formerly known as *Wegener granulomatosis*, are necrotizing granulomatous inflammation involving the upper and lower respiratory tract, necrotizing glomerulonephritis, and systemic necrotizing vasculitis affecting predominantly small to medium vessels (eg, capillaries, venules, arterioles, arteries, and veins).

Epidemiology

The annual incidence of GPA is 5 to 10 cases per million population equally affecting males and females between the ages of 65 and 70 years. The GPA affects Caucasians more than Asians, Africans, and the Afro-Caribbean and African American populations.

Pathobiology

The immunopathobiology of GPA is complex and involves the generation of ANCA against PR3 in approximately 50% to 80% of GPA patients and against MPO in approximately 10% to 18% of GPA patients. The GPA is believed to develop following exposure to infectious (bacterial, mycobacterial, fungal, or viral infections of the upper respiratory tract), environmental, chemical, toxic, or pharmacologic triggers in genetically predisposed individuals who lack tolerance to ANCA self-antigens.

Clinical Manifestations

Prodromal symptoms may last for weeks to months with constitutional symptoms including fever, migratory arthralgias, malaise, anorexia, and weight loss. The GPA has a predilection for the respiratory system and kidneys. According to criteria of the American Academy of Rheumatology, the diagnosis can be made if there are two of the following four criteria:

1. Oral ulcers or purulent bloody nasal discharge
2. Abnormal chest film showing nodules, fixed infiltrates, or cavities
3. Microscopic hematuria
4. Biopsy evidence of granulomatous inflammation in the wall of an artery or perivascular tissue

As with other vasculitic syndromes, GPA affects the peripheral nervous system in the form of a sensorimotor peripheral neuropathy (mononeuritis multiplex) more than the CNS. The CNS is affected in less than 10% of patients. In such cases, intracranial granuloma may arise following direct invasion from the nasal cavity and in turn involvement of the basal cranial nerves. Additionally, aseptic meningeal necrotizing granulomas, encephalopathy, or vasculitis with secondary stroke or venous sinus thrombosis may occur.

Diagnosis

Approximately 90% of patients are ANCA positive and 10% of patients are ANCA negative. The definitive diagnosis is made by biopsy of an affected organ (generally skin, kidney, or lung).

In patients with neurologic manifestations, involvement of the dura with pachymeningitis may be detected on MRI after contrast administration. Because the caliber of the affected vessels may be beyond the spatial resolution of digital subtraction angiography, radiologic confirmation of CNS vasculitis in Wegener granulomatosis is rare. Nerve biopsies may show arteritis in patients with polyneuropathy and no signs of systemic disease.

Management

Patients should be treated empirically if the clinical suspicion for ANCA vasculitis is high, and a tissue diagnosis cannot be obtained in a timely manner. Therapy of GPA has two components: induction of remission and maintenance using immunosuppressive therapy. Patients with mild disease lacking active glomerulonephritis and organ-threatening or life-threatening manifestations may be treated with a regimen of glucocorticoids in combination with *methotrexate*. Patients with moderate to severe disease who are at imminent risk for organ damage or who have life-threatening manifestations should receive a regimen consisting of glucocorticoids in combination with either *cyclophosphamide* (oral or intravenous) or *rituximab*. Plasma exchange is reserved for patients with GPA or MPA who have one or more of the following: pulmonary hemorrhage, a positive antiglomerular basement membrane antibody, a serum creatinine more than 5.7 mg/dL, and/or requiring dialysis.

Outcome

Long-term survival with GPA is improved with immunosuppression, and the natural history of this disease has transformed from being an imminently life-threatening condition to a chronic condition prone to relapse throughout life. Left untreated, approximately 90% of patients will experience severe morbidity or mortality within 2 years. Even with aggressive treatment, GPA continues to be associated with morbidity due to chronic renal, pulmonary, or CNS failure, which affects 12% to 25% of patients within 10 years. Death is generally due to irreversible organ dysfunction and progressive renal failure.

Eosinophilic Granulomatosis With Polyangiitis

Introduction

Eosinophilic granulomatosis with polyangiitis (EGPA), previously known as *Churg-Strauss syndrome*, is a multisystem disorder due to small-vessel vasculitis characterized by eosinophil-rich and necrotizing granulomatous inflammation often involving the respiratory tract and necrotizing vasculitis predominantly affecting small to medium blood vessels. Asthma and peripheral blood eosinophilia are other prominent features. Mononeuritis multiplex is the most common form of neurologic involvement.

Epidemiology

The exact incidence and prevalence of EGPA is unknown but it is rare: Estimates are in the range of 10 to 13 cases per million population. The mean age at diagnosis is 48 years without clear gender predominance. There is a higher incidence among asthmatics.

Pathobiology

EGPA is classified among the ANCA-positive vasculitides with several characteristics pointing to an immunologic etiology, which include the presence of elevated T_H1 and T_H2 lymphocyte function, increased eosinophil recruitment, decreased eosinophil apoptosis, and altered humoral immunity in the form of hypergammaglobulinemia and rheumatoid factor positivity. Genetic factors appear to play a role in the pathogenesis as implicated by the association with human leukocyte antigen class and certain interleukin-10 polymorphisms. Histopathologically, EGPA was originally described as a pathologic triad consisting of (1) necrotizing giant cell vasculitis, (2) eosinophilic tissue infiltration, and (3) extravascular necrotizing granuloma formation, but these characteristics rarely coexist in any one patient. Nerve biopsy may demonstrate epineural necrotizing vasculitis with accompanying eosinophil and lymphocyte infiltrates.

Clinical Manifestations

The American Academy of Rheumatology established six criteria for the diagnosis of EGPA in patients with documented vasculitis. These included the presence of (1) asthma, (2) eosinophilia, (3) a mononeuropathy or polyneuropathy, (4) migratory transient pulmonary opacities detected radiographically, (5) paranasal sinus abnormalities, and (6) biopsy containing a blood vessel showing eosinophil infiltrates in extravascular areas. The presence of four or more of these criteria had a sensitivity of 85% and a specificity of 99% for EGPA.

A peripheral neuropathy, usually mononeuritis multiplex, associated with severe neuropathic pain is seen in up to 75% of patients; other neurologic manifestations may include subarachnoid and intracerebral parenchymal hemorrhage and cerebral infarction, but these are rare.

Diagnosis

A high index of suspicion is necessary for the diagnosis of EGPA. Tests to rule out CNS vasculitis should be performed (see Table 43.3). Most patients with EGPA have peripheral blood eosinophilia, although this may be obscured by use of systemic glucocorticoids to control asthma. The ANCAs are noted in 40% to 60% of EGPA patients with the majority being MPO ANCA. Typical findings on chest high-resolution computed tomography include patchy parenchymal consolidation or ground-glass opacification; nodules may also be noted.

Management

Systemic glucocorticoids are the cornerstone in EGPA therapy and are usually continued for 6 to 12 weeks and then gradually tapered. *Prednisone* 60 mg daily is a typical starting dose. Patients with severe disease with CNS or cardiac involvement require induction with *cyclophosphamide* in combination with systemic glucocorticoid therapy. Induction is followed by a transition to maintenance therapy with azathioprine or methotrexate and leflunomide to induce disease remission over 12 to 18 months; longer courses are necessary for patients with multiple relapses.

Outcome

With the use of systemic glucocorticoids and immunomodulatory medication, the prognosis of EGPA has improved dramatically from a 50% mortality rate among untreated patients within 3 months of onset to a 70% to 90% 5-year survival rate with aggressive therapy. Death usually occurs secondary to cardiac failure, myocardial infarction, renal failure, cerebral hemorrhage, gastrointestinal bleeding, or status asthmaticus.

Microscopic Polyangiitis

Introduction

In MPA, a necrotizing vasculitis with few or no immune deposits predominantly affects small vessels (ie, capillaries, venules, or arterioles) throughout the body. Necrotizing glomerulonephritis is very common, pulmonary capillaritis is common, and neurologic involvement occurs in about half of cases. Granulomatous inflammation is absent.

Epidemiology

The exact incidence and prevalence of MPA are unknown, although the incidence has been estimated to be in the range of six cases per million population affecting men slightly more than women, with an age range of 60 to 65 years.

Pathobiology

As with GPA, the immunopathobiology of MPA is complex; there is increasing evidence that MPA is an autoimmune disease, with ANCA antibodies positive in 95% of cases. The pathophysiology involves the generation of ANCA against MPO in approximately 70% and against PR3 in 30% of MPA patients. The ANCA, directed against MPO and PR3, activates neutrophils to produce reactive oxygen species and release lytic enzymes causing the detachment and destruction of endothelial cells contributing to the pathophysiology.

Clinical Manifestations

As with all other systemic vasculitides, multiple organs are affected with MPA, primarily the kidneys in 90% of cases and less frequently the lungs. Renal involvement is manifested by microscopic hematuria and rapidly progressive glomerulonephritis; 10% progress to end-stage renal disease requiring renal replacement therapy. Pulmonary manifestations range from dyspnea, cough, and hemoptysis to pulmonary hemorrhages, secondary to pulmonary capillaritis, which can be life-threatening. In contrast to GPA, MPA lacks granulomatous inflammation and involvement of the upper respiratory tract. The nervous system is involved in 50% of cases, with polyneuropathy or mononeuritis multiplex being the most common manifestation. Cerebral vasculitis resulting in tissue ischemia, hemorrhage, encephalopathy, and generalized or focal seizures can also occur.

Diagnosis

Tests to rule out CNS vasculitis should be performed as delineated in Table 43.3. Microscopic hematuria with cellular casts in the urine in addition to proteinuria may be demonstrated on urinalysis. An important diagnostic test is the presence of perinuclear antineutrophil cytoplasmic antibody against with MPO or PR3. In patients with neuropathy, an electromyogram may reveal a sensorimotor peripheral neuropathy.

Management and Outcome

The treatment and outcome of MPA is generally the same as that for GPA, as described earlier.

Immunoglobulin A Vasculitis Henoch-Schönlein Purpura

Immunoglobulin A vasculitis (IgA vasculitis, IgAV; formerly called Henoch-Schönlein purpura) involves skin, joints, kidneys, and gastrointestinal tract. Single reports and case series document neurologic manifestations due to small vessel vasculitis in children with IgAV (Henoch-Schönlein purpura) including headaches, seizures, encephalopathy (both hypertensive encephalopathy and posterior reversible encephalopathy syndrome), focal neurologic deficits, ataxia, intracerebral hemorrhage, and central and peripheral neuropathy. The IgAV is usually a self-limiting disease. Pulse corticosteroid therapy is widely used as the first-line treatment and has proven to be effective in most patients

Cryoglobulinemic Vasculitis

Cryoglobulinemic vasculitis is characterized pathologically by deposition of cryoglobulins and complement in small-vessel lumens and walls leading to vessel inflammation. The clinical and pathologic manifestations of cryoglobulinemic vasculitis overlap with those of other systemic vasculitides. The peripheral nervous system is often involved in patients with mixed cryoglobulinemia, whereas there are only few reports of CNS involvement.

Variable-Vessel Vasculitis

Behçet Syndrome

Introduction

Behçet syndrome is a chronic, multisystem vessel vasculitis that has no predilection to the type or size of vessel. Neurologic involvement occurs in about one in five patients.

Epidemiology

Behçet syndrome is most common in the Middle East and Eastern Asia with prevalence ranges from 13.5 to 35 per 100,000. In North American and Northern European countries, the prevalence is from 1 to 7 per 100,000. There is no gender predilection; the disease typically affects young adults 20 to 40 years of age.

Pathobiology

The exact cause is unknown, but there is increasing evidence that an underlying immune-mediated vasculitis underlies the mucocutaneous lesions. Although vasculitic changes may not be demonstrated in all lesions, the classic finding is a necrotizing leukocytoclastic obliterative perivasculitis with fibrinoid necrosis of postcapillary venules. Venous thrombosis with lymphocytic infiltration of capillaries, veins, and arteries of all sizes may also be visible. It has been reported that those with active Behçet syndrome have elevated serum levels of several proinflammatory cytokines, perhaps as a result of an aberrant immune reaction due to infectious or environmental pathogens. Numerous reports have found a strong genetic predisposition to develop Behçet disease among those with the HLA-B51 major histocompatibility complex subtype.

Clinical Manifestations

Behçet syndrome is characterized by uveitis and recurrent oral and genital aphthous ulcers. Other manifestations include ocular, cutaneous, joint, gastrointestinal, or CNS inflammatory lesions. Small-vessel vasculitis, thromboangiitis, vessel thrombosis, arteritis, and arterial aneurysms may occur. The CNS involvement is present in 20% of patients and can be subdivided into parenchymal (inflammation of the CNS tissue) or nonparenchymal (vascular neuro-Behçet).

Parenchymal disease may be due to lesions in the corticospinal tract, periventricular white matter, basal ganglia, brainstem, and spinal cord. Clinical presentations are often subacute and manifestations may include headache, behavior changes, encephalopathy, acute meningeal syndromes, hemiparesis, hemisensory loss, seizures, cranial neuropathies, cerebellar dysfunction, alterations in mental status, and optic neuropathy. Spinal cord lesions may occur in isolation. Vascular manifestations may include diffuse vasculitis, venous sinus thrombosis, and uncommonly stroke due to arterial thrombosis, dissection, or aneurysm. In contrast to other systemic vasculitides, peripheral neuropathy is not commonly seen in Behçet syndrome.

Diagnosis

Due to the lack of a specific diagnostic laboratory test, the diagnosis is made based on clinical criteria. The Behçet International Study Group criteria and the International Criteria for Behçet's Disease both require the presence of recurrent oral ulcers in addition to a constellation of recurrent genital ulcers, eye lesions (anterior or posterior uveitis or retinal vasculitis), or skin lesions (including erythema nodosum, pseudovasculitis, papulopustular lesions, or acneiform nodules consistent with Behçet). The International Criteria for Behçet's Disease also adds the presence of vascular lesions (superficial phlebitis, deep vein thrombosis, arterial thrombosis, or aneurysm formation) to the diagnostic criteria. Nonspecific markers of inflammation such as proinflammatory cytokines, circulating immune complexes, C reactive protein, and the ESR may be elevated.

Management

Treatment is dependent on the severity of the disease and the organ systems involved. Glucocorticoids or other immunosuppressive agents should be considered for treatment of erythema nodosum and pyoderma gangrenosum. Posterior uveitis and neurologic involvement requires prompt treatment with both high-dose glucocorticoids and a second immunosuppressive agent (*azathioprine*, *tumor necrosis factor α inhibitors*, *cyclosporine*, *interferon α*, *cyclophosphamide*, and *methotrexate*).

Outcome

Behçet syndrome typically has a relapsing and remitting course. Delay in diagnosis and treatment increases morbidity and mortality. The greatest morbidity and mortality comes from neurologic, ocular, and large-vessel arterial or venous disease. Mucocutaneous, articular, and ocular diseases are often at their worst in the early years of disease; CNS and large-vessel involvement tends to develop later in the disease course. Patients with parenchymal CNS involvement have a worse outcome than patients with nonparenchymal vascular involvement, with more frequent recurrent disease, disability, and premature death.

Cogan Syndrome

Cogan syndrome is a rare autoimmune systemic vasculitis characterized by nonsyphilitic interstitial keratitis and audiovestibular symptoms that resemble Meniere disease (sudden onset of tinnitus, nausea and vertigo, accompanied by gradual hearing loss), and neurologic involvement has been described in literature based on biopsy results.

Cogan syndrome is a rare disease, which primarily affects young adults but can affect children also, the age of onset ranging from 3 to 50 years have been published. The average age of disease onset is second decade. There are fewer than 250 reported cases in literature, and it is mostly described in Caucasian patients of both sexes.

In 1980, Haynes and coauthors proposed the classification of Cogan syndrome as "typical" Cogan syndrome and "atypical" Cogan syndrome (chronic and recurrent conjunctivitis, scleritis, uveitis, optic disc edema, and retinal vasculitis).

The diagnosis should be suspected when patients present with ocular abnormalities along with audiovestibular symptoms. Clinically, vasculitis has been reported to affect the skin, kidneys, distal coronary arteries, CNS, and muscles. Autopsies have revealed vasculitis in the dura, brain parenchyma, gastrointestinal system, kidneys, spleen, aorta, and the coronary arteries. Pathologic examinations of the proximal portion of the aorta in patients with Cogan syndrome have shown generalized dilatation and narrowing of the coronary arteries in the region of the aortic valve. No serologic marker for the disease has been found, so it is a diagnosis of exclusion.

Corticosteroids are the first line of treatment and can aid in the recovery of hearing if they are administered early in the disease course. In some cases, immunosuppressive drugs have proven to be effective. The most recent therapeutic options are tumor necrosis factor α blockers.

Patients without systemic involvement have a good prognosis with average life expectancy, whereas patients with serous vasculitis have an increased risk of death due to complications.

Vasculitis Associated With Systemic Disease

CNS Vasculitis in Rheumatoid Arthritis

CNS involvement in rheumatoid arthritis is not common. The most frequent neurologic manifestations of rheumatoid arthritis are peripheral neuropathy and cervical spinal cord compression due to subluxation of the cervical vertebrae. Cerebral rheumatoid

vasculitis is an uncommon complication, which is associated with high morbidity.

The rate of occurrence of cerebral vasculitis in patients with rheumatoid arthritis is 1% to 8%. Neurologic involvement includes atlantoaxial subluxation, polymyositis, mononeuritis multiplex, peripheral neuropathy, rheumatoid nodules in the central or peripheral nervous system, and rheumatoid vasculitis causing stroke and/or neuropathy.

It has been described traditionally in seropositive patients with long-standing, active and erosive rheumatoid arthritis, with subcutaneous nodules and extra-articular manifestations. Catheter angiogram and biopsy is the gold standard for diagnosis.

Glucocorticoids are used in the treatment of CNS rheumatoid vasculitis. Several alternatives such as azathioprine, intravenous immunoglobulins, and cyclophosphamide are available for patients with corticosteroid-resistant or contraindicated vasculitis. Prognosis is generally poor.

CNS Nervous System Vasculitis in Systemic Lupus Erythematosus

CNS vasculitis secondary to systemic lupus erythematosus (SLE) is a rare diagnosis. The exact pathogenesis of the vasculopathy and the vasculitis is not known, and it is possible that the entity constitutes multiple overlapping pathomechanisms. Certain autoantibodies associated with ischemic and inflammatory pathways may be involved in the pathogenesis.

In SLE, neurologic damage can be a result of direct antibody-mediated tissue damage or damage to the vessels supplying the tissues (cerebral vasculitis). However, there is little histologic support for lupus cerebritis. Vasculopathy on the other hand is seen often in SLE.

MISCELLANEOUS CAUSES AND MIMICS OF CENTRAL NERVOUS SYSTEM VASCULITIS

Reversible Cerebral Vasoconstriction Syndrome

Formerly known as *Call-Fleming syndrome*, RCVS is a monophasic self-limited acute cerebral vasoconstriction syndrome (see Chapter 44 for a full discussion). Patients typically present with headache and may develop minor neurologic deficits related to vasogenic edema or small infarcts, seizures, or convexity subarachnoid hemorrhage. Classic beading is seen on digital subtraction angiography that can be indistinguishable from PACNS. The important differences between RCVS and PACNS are that the former syndrome tends to be much more benign and self-limited. Misdiagnosis of RCVS as PACNS (Table 43.4) and treatment with immunosuppressive agents is not warranted because the condition results from myogenic arterial spasm rather than an autoimmune process causing intramural vessel inflammation. Apart from use of calcium channel blockers such as oral nimodipine 60 mg every 4 hours, treatment is supportive and spontaneous recovery over several weeks is the rule.

Intravascular Large Cell Lymphoma

Intravascular large B-cell lymphoma (IVLBCL) is a rare type of non-Hodgkin lymphoma classified by the World Health Organization as an extranodal diffuse large B-cell lymphoma (LBCL) characterized by the selective growth of neoplastic lymphocytes

TABLE 43.4 Differentiating Primary Angiitis of the Central Nervous System and Reversible Cerebral Vasoconstriction Syndrome

	PACNS	RCVS
Gender predominance and mean age at onset	Male, 50 y	Female, 40 y
Onset and clinical presentation	Insidious with subacute to chronic onset of headache with focal and nonfocal deficit	Acute onset of thunderclap headache with or without neurologic deficit
Clinical course	Chronic, relapsing	Remission within 1 mo, monophasic
Headache	Progressive, dull aching	Severe, throbbing, often thunderclap
CSF findings	Abnormal lymphocytic pleocytosis and elevated protein levels	Normal to near normal
Diagnosis	Leptomeningeal and brain parenchymal tissue biopsy necessary	No biopsy indicated
Common neuroimaging findings	Ischemic, high-intensity T2/FLAIR lesions abnormal MRI scans in 100 % of cases	Ischemic, edema, convexity subarachnoid hemorrhage, ICH normal MRI images in 20% of cases
Vascular findings	Normal in one-third of cases. Diffuse abnormalities are often indistinguishable from RCVS; irregular and asymmetric arterial stenoses or multiple occlusions are more suggestive of PCNSV; abnormalities might be irreversible.	Abnormal in all cases; strings of beads appearance of cerebral arteries; abnormalities reversible within 6-12 wk
Histologic findings	Vasculitic changes	Normal
Drug treatment	Glucocorticoids with or without cytotoxic agents	Nimodipine; no glucocorticoids
Immunosuppressive therapy	Essential	Not indicated
Prognosis	Improved with immunosuppressive therapy	Excellent

Abbreviations: CSF, cerebrospinal fluid; FLAIR, fluid-attenuated inversion recovery; ICH, intracranial hemorrhage; MRI, magnetic resonance imaging; PACNS, primary angiitis of the central nervous system; PCNSV, primary central nervous system vasculitis; RCVS, reversible cerebral vasoconstriction syndrome.

within blood vessel lumina of small vessels, particularly capillaries and venules. This type of lymphoma has also been described as *intravascular lymphomatosis*, *angiotropic large cell lymphoma*, and *malignant lymphangioendotheliomatosis*. The IVLBCL is not a form of vasculitis per se but is often included in the differential diagnosis of PACNS because it can cause a rapidly progressive pattern of widespread brain infarction in a patient without risk factors for cerebrovascular disease.

Epidemiology

The incidence of IVLBCL is unknown; the median age at diagnosis is in the sixth to seventh decades with no gender predilection.

Pathobiology

The diagnosis of IVLBCL is made by demonstrating large lymphoid cells with high mitotic activity within small to medium blood vessels.

Clinical Manifestations

The clinical presentation is varied and often includes symptoms related to organ dysfunction caused by occlusion of small blood vessels. Constitutional symptoms are seen in 55% to 85% of patients. The IVLBCL is considered a disseminated disease at diagnosis frequently manifesting with CNS and cutaneous symptoms in Western countries or with hemophagocytic syndromes in Asian countries. Rapidly progressive, recurrent ischemic strokes and peripheral neuropathies are frequently seen. The CNS symptoms may include progression from lethargy to coma, focal neurologic deficits, seizures, or central hyperventilation. Neurologic symptoms are less commonly seen in patients of Asian descent who frequently present with involvement of the bone marrow, spleen, and liver.

Diagnosis

A wide range of laboratory abnormalities may be seen, ranging from elevated lactate dehydrogenase, β_2-microglobulin, and ESR levels to abnormal liver, renal, or thyroid function tests; anemia; thrombocytopenia; and hypoalbuminemia. The CSF analysis only rarely demonstrates malignant cells, but CSF cytology and flow cytometry should be obtained. The IVLBCL is not typically associated with an obvious extravascular tumor mass, adenopathy, or detectable circulating lymphoma cells in the peripheral blood.

Brain biopsy or deep skin biopsy including the subcutaneous tissues is necessary to confirm the diagnosis. The bone marrow, lymph nodes, peripheral blood, and CSF are often uninvolved. Cerebral MRI findings include infarctions when occlusions occur in small arteries, patchy foci of white matter hyperintensities when the pathology involves the capillaries, mass-like lesions, and thickening of the meningeal vessels with meningeal or focal parenchymal enhancement.

Treatment and Outcome

Accurate and timely diagnosis of IVLBCL is still a problematic issue, and many cases are diagnosed at autopsy. However, in recent years, the heightened awareness of IVLBCL with appropriate investigations has resulted in more patients being diagnosed during life. Treatment of patients with IVLBCL includes a combination of *cyclophosphamide*, *doxorubicin*, *vincristine*, and *prednisone* with *rituximab*, a recombinant anti-CD20 monoclonal antibody (R-CHOP). The addition of *rituximab* has been shown to improve progression-free 2-year survival from 27% to 56%.

Infectious Central Nervous System Vasculitis

Infection is a well-recognized cause of CNS vasculopathy that can mimic autoimmune PACNS. The spectrum of infections that can cause segmental vascular inflammation of the cerebral arteries ranges includes viruses (eg, varicella-zoster virus or hepatitis C; see Chapter 69), bacterial meningitis or endocarditis (see Chapter 64); chronic meningitis due to tuberculosis, spirochete infection (eg, neurosyphillis), or fungal infection (eg, *Aspergillus*, *Cryptococcus*; see Chapter 67); rickettsial infection (eg, Rocky Mountain spotted fever; see Chapter 66); and parasites (see Chapter 68). In most cases, the process is believed to be due to direct invasion and proliferation of pathogens in vessel walls with resultant inflammation, although some may develop as a result of an autoimmune response initiated by exposure to a pathogen (eg, cryoglobulinemic vasculitis in the setting of HCV infection).

Varicella-zoster virus is a frequent cause of viral CNS vasculitis affecting large vessels in immunocompetent hosts while causing a more extensive protracted disease in immunocompromised individuals by affecting small vessels. Hepatitis C has been associated with small-vessel vasculitis related to mixed cryoglobulinemia, which accounts for the majority of cases, or a small- to medium-vessel vasculitis similar to PAN.

Bacterial cerebral vasculitis usually starts as purulent infection at the base of the brain progressing to inflammatory cell infiltration of vessel walls, with subsequent septic thrombosis and thrombophlebitis manifesting clinically as ischemic stroke and hemorrhages. Syphilitic vasculitis usually occurs as part of tertiary syphilis and occurs for 10% to 40% of untreated cases. Diffuse syphilitic vasculitis preferentially involves the cortical arteries and veins, whereas the gummatous vasculitis usually affects proximal middle cerebral artery branches. Classic angiographic findings include narrowing of the proximal portions of the cerebral arteries with distal beading due to alternating segmental stenoses and dilatations.

The CNS tuberculosis is frequently associated with segmental infectious vasculitis, secondary aneurysm formation, and thromboses causing infarctions of the basal ganglia, cerebral cortex, brainstem, and cerebellum in patients with CNS tuberculosis.

Drug-Induced Central Nervous System Vasculitis

Although the exact incidence and pathobiology is unknown, there is ample evidence that some illicit and therapeutic drugs can result in either a self-limited or more protracted form of cerebral vasculitis. The pathogenesis is likely multifactorial. Drugs with sympathomimetic activity (*amphetamines*, *cocaine*, *phenylpropanolamine*) have been frequently implicated in causing biopsy-proven inflammatory cerebral vasculitis as well as ischemic stroke precipitated by noninflammatory cerebral vasoconstriction.

The clinical diagnosis is one of exclusion based on the temporal relationship between the administration of the offending drugs and clinically evident vasculitis. Management is generally supportive in addition to removal of the instigating agent, which alone is often sufficient to induce prompt resolution of clinical manifestations. There is little data to guide management of severe cases where there is vital organ involvement.

Fibromuscular Dysplasia

Fibromuscular dysplasia (FMD) involves small- and medium-sized arteries. It is a noninflammatory, nonatherosclerotic angiopathy that occurs most commonly in women. FMD can mimic vasculitis angiographically but is usually asymptomatic and rarely has a severe clinical course. The most common clinical manifestation of FMD is dissection due to vessel wall degeneration. Isolated cases of FMD have been reported mimicking the following conditions: PAN, Ehlers-Danlos syndrome, Alport syndrome, pheochromocytoma, Marfan syndrome, and Takayasu arteritis. The etiology of FMD remains unknown. The major sites affected are renal, cerebral, carotid, visceral, iliac, subclavian, brachial, and popliteal arteries. The diagnosis of FMD is made by histopathology and/or angiography.

Characteristic findings on angiography are described as "string of pearls" or beads on a string appearance. Treatment may include revascularization in certain circumstances.

44 Posterior Reversible Encephalopathy Syndrome and Other Cerebrovascular Syndromes

Claire S. Riley, Sara K. Rostanski, and Joshua Z. Willey

POSTERIOR REVERSIBLE ENCEPHALOPATHY SYNDROME

KEY POINTS

1. Posterior reversible encephalopathy syndrome results from failure of autoregulation leading to hyperperfusion with cerebral dysfunction.
2. A large majority of patient with posterior reversible encephalopathy syndrome will also have cerebral vasospasm and there is substantial overlap with reversible cerebral vasoconstriction syndrome (RCVS).
3. The pattern of edema is posterior predominant but can affect multiple structures and the changes can become permanent leading to cerebral infarction.
4. Treatment includes reversal of the underlying cause and supportive care.

Introduction

The posterior reversible encephalopathy syndrome (PRES) has been evolving as a clinical entity for at least two decades with significant confusion as to what the syndrome is. Several terms have now been used interchangeably to define PRES, including *reversible posterior leukoencephalopathy syndrome*, although the terminology itself is not specific given the syndrome is not always posterior and not always reversible. The PRES is now recognized as a syndrome defined by clinical and radiologic features with multiple different etiologies but which shares several common features with the reversible cerebral vasoconstriction syndrome (RCVS).

Epidemiology

Limited data exist to describe the epidemiology of this condition. The literature has mostly been centered around case reports and case series.

Pathobiology
